Forest health refers to the production of forest conditions which directly satisfy human needs and by resilience, recurrence, persistence, and biophysical processes which lead to sustainable ecological conditions. Thus, forest health refers to a condition of ecosystem sustainability and attainment of management objectives for a given forest area; usually considered to include green trees, snags, resilient stands growing at a moderate rate, and endemic levels of insects and disease.

The health of national forests and grasslands is paramount to our mission of caring for the land and serving people. The Forest Service works to maintain, enhance, and restore healthy forest conditions on the national forests and grasslands.

Forest Land

A forest is an area of land dominated by trees and spanning more than (approximately) 1.2 acres with trees higher than 16 feet and a canopy cover of more than 10%, or trees able to reach these thresholds in situ. Forest trees can be of any size, including land that formerly had such tree cover and that will be naturally or artificially regenerated; includes transition zones, such as areas between heavily forested and non-forested lands with forest trees and forest areas adjacent to urban and built-up lands; also included are pinyon-juniper and chaparral areas; the minimum area for classification of forest land is 1 acre. The six types of forest are: (i) equatorial moist evergreen or rainforest, (ii) tropical deciduous forest, (iii) Mediterranean forests, (iv) temperate broad-leaved deciduous and mixed forest, (v) warm temperate broad-leaved deciduous forest, and (vi) coniferous forest.

Forests filter out pollutants and particulates so that citizens pay less to treat their drinking water. Another way tree-covered landscapes help is by soaking up rainwater, releasing it slowly over time, and reducing the amount of runoff that causes rivers and streams to flood.

See also: Forest Health, Forest Residues, Wood.

Forest Residues

Material not harvested or removed from logging sites in commercial hardwood and softwood stands as well as material resulting from forest management operations such as precommercial thinnings and removal of dead and dying trees.

Forestry residues are produced when controlled thinning of plantations and trimming of felled trees is undertaken to reduce forest fire risk and to accelerate the forest growing rate that can sometimes be prevented if the area is overpopulated. This waste is usually just left to rot on the forest ground; extracting and collecting it clear up the forest making it easily accessible and manageable. In this category, waste from public gardens and woods can also be included. The waste can be collected, dried, and used as fuel.

Young forests sometimes get too dense. Thinning these forests helps the trees to grow into a more valuable and better-quality forest. The fining process can be carried out manually or automatically with wood collectors. The whole tree received from the thinning consists of a small diameter stand wood, branches, leaves, and needles and provides a significant energy potential for solid biofuels.

In most countries, forest slash is still not used whereas in Finland, Sweden, and a couple of other countries, this energy resource is largely utilized. These residues are the main source of forest fuels from the final felling of trees. At the felling areas, for every m³ of solid industrial wood, the residual biomass generated amounts from 35 to 45%. Forest slash mainly consists of the tops of trunks, stems, branches, leaves, stumps, and roots and when discharged can cause environmental problems and the loss of a natural resource. Logging residues can be effectively used with a new bundling technology.

Stumps and roots are a major unexploited resource of forest logging residues. They consist more than 20% of a harvestable dry mass of a tree. In regeneration cuttings, the full yield from stumps has turned to be as high as from aboveground residues. The stump harvesting, handling, and crushing technology is becoming cost competitive, and the quality of these chips meets the requirements set for fluidized bed boilers. Silvicultural works related to removing stumps are becoming easier to handle and cost-effective.

Fossil Fuel Resources

Fossil fuels are those fuels, namely, coal, crude oil (including heavy crude oil and extra heavy crude oil, and tar sand bitumen), natural gas, and oil shale are produced by the decay of plant remains over geological time. These fuels are carbon-based and represent a vast source of energy. In fact, at the present time, the majority of the energy consumed by humans is produced from the fossil fuels, coal, crude oil, and natural gas with smaller amounts of energy coming from nuclear and hydroelectric sources.

Planning for the future use of these materials requires (as it does for any resource) an estimate of the amounts of fossil fuels which remain. However, the estimates of the fossil fuels available for future use differ considerably. The issue lies with the use of so-called undiscovered reserves (or reserves-yet-to-be-discovered) of the fossil fuels, but suppositions that there are yet-to-be-discovered reserves of fossil fuels is open to much debate and many questions.

In terms of resource availability, it is a matter of understanding (i) the amount of a resource that is available, (ii) recovery of the resources with the maximal efficiency, and (iii) the application of recovery methods that will cause minimal damage to (disturbance of) the environment. Estimates of the quantities of recoverable fossil fuels in the world vary and are subject to much speculation because of the loose definition of the term resource.

Apart from providing the major source of energy for industrial and domestic consumption, fossil fuels also provide, in many cases, the means (energy) by which other resources can be recovered and converted to products for consumer use. Therefore, it is worthwhile at this point giving consideration to the impact of fossil fuels not only on the evolution of science and engineering (in fact, on the progress of technology in general) but also on the environment with some indication of the steps that will be necessary to ensure reductions in emissions from the use of such fuels (Walker and Wirl, 1994).

First, and to reemphasize, fossil fuels are not the only source of pollutants but they are a major source of energy. As such, the use of fossil fuels has been the cause for considerable criticism but it is not the fuel that is at fault.

It is the manner in which the fuels are used and has been due to lack of environmental-related oversight during the production of energy from the fuel. Thus, it is necessary to reconsider the strategies for fossil fuel use whereupon it may be discovered (again!) that fossil fuels can be used in an environmentally acceptable manner. Hence, it is necessary to understand, by way of background, the various types of fossil fuels that generate energy and the evolution of their use in this present time. This will also aid in understanding the means by which fossil fuels can produce noxious emissions. Such an understanding will then lead to means by which the emissions can be reduced, if not eliminated completely.

In summary, understanding the nature of fossil fuels and their recovery from the formation in which they exist can be equated to the recovery of any mineral and its use as a commodity. There is also the need to understand the influence of the various processes on the ecological cycles as well as, in many cases, the potential for the production of acid rain and the potential for global warming, or any similar effect.

Thus, understanding the resource is a benefit to an understanding the recovery processes and the conversion processes through an evaluation of the products and the effects on the environment of the recovery process and manufacture of the products.

Fouling

Fouling is the accumulation of small, sticky molten particles of ash on a boiler surface. It is the buildup that occurs in the lower temperature regions of the combustion system. It affects the design and maintenance of superheaters, reheaters, and furnace water walls. Fouling has been found to be related to the alkaline content of ash, although the total quantity of alkali is not necessarily an accurate index of fouling potential. Sodium in ash has been found to be a key link in the fouling formation. Specifically, the vapor-phase sodium in the combustion gases promotes contact and subsequent bonding between ash particles and metal surfaces as gas cools and the sodium condenses. The high-alkali ash found in many biomass feedstocks has been linked to a rapid buildup of deposits, which influences the design of tube spacing in convective passes.

Ash is composed mostly of metal oxides, and the composition affects the softening point. Iron oxides are a particular source of problems, and the reducing atmosphere ($\text{CO} + \text{H}_2$; produced by the water gas reaction) in the fuel bed serves to reduce ferric oxide (Fe_2O_3) to ferrous oxide (FeO) with the production of clinker which will contribute to reactor fouling.

In addition, the fouling of combustion systems has also been related to the alkali metals content of the carbonaceous feedstock. For example, a carbonaceous feedstock with a total alkali metal content $<0.5\%$ w/w (as equivalent sodium oxide, Na_2O) produces deposits that can be removed by the action of soot blowers (perforated lances through which jets of high-pressure air or steam can be sent between boiler tubes), but for the carbonaceous feedstock having more than 0.6% w/w alkali metal (as equivalent sodium oxide), the deposits increased markedly and can be a major problem.

To combat fouling, modern combustion equipment is designed to ensure that particles are cooled to well below their fusion temperatures before they can reach the banks of closely spaced tubes in the upper regions of the boiler. In pulverized fuel systems, provision is usually made for tilting the burners and thereby periodically altering the heat regime. In addition, tube deposits are routinely dislodged by frequent soot blowing.

See also: Fouling Tendency.

Fouling Tendency

Fouling tendency is the potential for a fuel to form unwanted insoluble deposits during the course of its operation. Usually, the deposits are carbonaceous in nature. These deposits, in turn, can degrade system performance by causing less efficient heat exchange, plugging, and other problems, which may ultimately lead to system failure. All fuel systems are subject to some degree of fouling. Some fuel systems addressed in this article are (i) military aircraft,

(ii) drop tube furnaces, (iii) fluidized bed combustors, (iv) solid fuel combustors, (v) biomass boilers, and (vi) ethylene furnaces.

Fouling tendency is unique to each fuel system and is dependent on a variety of factors which are of varying importance from system to system. In addition, each system may experience different fouling mechanisms in different parts of the system. Some factors that influence fouling tendency include (i) the chemical properties and reactivity of the fuel used in the system operation, (ii) the design of the system, temperature, (iii) the heat flux, materials comprising the system, (iv) the pressure, (v) the flow rate and residence time, (vi) the size of particles in the fuel, and (vii) the length of time the system is operated.

The fouling tendency of a fuel is dependent on the unique chemistry of the fuel used in the system. In the case of most jet fuels, for example, alkanes and aromatics are the major components of the fuel, but trace amounts of polar species in the fuel containing oxygen, nitrogen, and or sulfur have the greatest effect on fouling. Fouling is also influenced by the presence of low levels of dissolved metals in the fuel. These metals typically act as initiators in the fuel's free radical chemistry, ultimately leading to faster formation of deposits. In jet fuel, the deleterious effect of copper is especially noteworthy. In a drop tube furnace, alkali and alkali-earth elements, especially sodium, have been linked to fouling. The presence of gases, such as dissolved oxygen, in the fuel also has an important effect on fouling. The presence of oxygen is related to the fouling process, though the total amount of deposit produced from this free radical process is fuel dependent. In fluidized bed combustion, the chemical makeup of the fuel, be it peat, forest residue, or willow, greatly influences fouling processes. Also, the age of the fuel has some bearing on its fouling tendency. An older fuel will typically have had more time to chemically react with its solid, liquid, and/or gaseous environment, and hence may pick up elements, such as minerals, which encourage fouling. This is true for FBC boiler fuels studied.

Fuel systems are often designed with the fouling tendency of a typical system fuel in mind. Where and when fouling will occur is dependent in part on an individual system's geometry. A change in flow direction or diameter, or any change in flow path in the system may influence the location of surface deposits. Fouling tends to reliably occur in certain parts of a given system. In a drop tube furnace studied, for example, fouling often occurred in the convective section. For a flowing system, a small opening for flow will generally result in more detrimental fouling problems—i.e., plugging—than a large opening. In aircraft, for example, the spray nozzle openings are small and blockage or change of the spray pattern due to partial plugging are important problems.

The temperature at which reactions occur is also important to fouling tendency. In many but not all cases, the higher the temperature, the worse fouling becomes. However, the amount of time the fuel is exposed to a given temperature and the amount of dissolved oxygen available greatly influence the effect of temperature on fuel fouling. Because of this, a particular flow path at a given temperature may equal a faster rate of fouling than another flow path at that temperature. For example, a military fighter aircraft at idle conditions will experience more fuel recirculation, which may form more deposition precursors and speed up the fouling process, than in the case where the aircraft is at full thrust. Also, cooling, especially an abrupt cooling, may encourage deposits to fall out, increasing the fouling tendency of a given system. This is true for a biomass boiler studied.

The fouling tendency of the fuel in a particular system is also dependent on the materials which comprise the system. Fuel in contact with different kinds of metals may produce different amounts of surface deposition. Also, fuel in contact with a surface that is more chemically inert, such as with a polysiloxane layer, will produce considerably fewer deposits than a fuel that is in contact with a more chemically active surface, such as a metal one.

Increasing pressure in a fuel system may or may not increase fouling. Whether pressure has an effect on fouling seems to depend on other specific reaction conditions, such as temperature and residence time. The effect of pressure probably has the most to do with whether a system is completely pyrolytic or not (that is, the entire reacting fuel and wall are at 300°C or greater), and whether dissolved oxygen is still present in the fuel. Some systems are more sensitive to pressure effects than others. For example, systems which produce gas, such as ethylene furnaces, typically experience an increase in fouling with increased pressure.

Generally, the lower the flow rate of the system, the greater the fouling tendency. For instance, systems using crude oil, atmospheric tower bottoms, and vacuum tower bottoms are subject to greater fouling with slower flow. The amount of fouling is dependent on the amount of time a fluid stays in a reaction zone. This time of occupation is called residence time. Flow rate is inversely proportional to residence time. The longer the fluid resides in the reaction zone, the more reaction will occur and the greater the deposition will be for the fuel.

The greater the size of the particles in the fuel flow, the greater the fouling tendency of the fuel tends to be. Large particles can be present in the unstressed fuel, contributing to fouling by plugging injectors or filters more easily, or large particles can be made during thermal stressing of the fuel. In the latter case, small particles in the fuel of the same type can stick to one another and form larger particles, and these in turn stick together and eventually form a mass of solid matter which becomes a layer of deposit on the wall. This type of deposit, usually made of a number of aromatic molecules joined together, is often referred to as soot. If this process is inhibited, for example by addition of a dispersant additive which prevents particle growth, significantly less fouling will typically be observed. Particle size also can affect where and when fouling occurs.

See also: Fouling.

Fractional Composition

The fractional composition of a fuel or a fuel source is the composition as determined by fractionation (separation) methods. The methods usually involve the separation of crude oil into two-to-five bulk fractions. The general procedure is to employ techniques that segregate the constituents according to molecular size and molecular type.

Various analytical techniques have been developed for the identification and quantification of every molecule in the lower boiling fractions of crude oil, and, as a result, it is recognized that the name crude oil does not describe a composition of matter but rather a mixture of various organic compounds that includes a wide range of molecular weights and molecular types that exist in balance with each other.

The fractional composition of crude oil varies markedly with the method of isolation or separation, thereby leading to potential complications (especially in the case of the heavier feedstocks) in the choice of suitable processing schemes for these feedstocks. Crude oil can be fractionated into three or four general fractions: (i) the asphaltene fraction, (ii) the resin fraction, (iii) the aromatics fraction, and (iv) the saturates fraction. Thus, it is possible to compare inter-laboratory investigations and thence to apply the concept of predictability to refining sequences and potential products.

Investigations of the character of crude oil through fractionation studies has been practiced since at least 1837, although modern fractionation techniques are essentially a twenty-first century approach to examining crude oil composition.

The success of any attempted fractionation procedure involves not only the application of one particular technique but also the utilization of several integrated techniques, especially those techniques involving the use of chemical and physical properties to differentiate among the various constituents. For example, the standard processes of physical fractionation used in the crude oil industry are those of distillation and solvent treatment, as well as adsorption by surface-active materials. Chemical procedures depend on specific reactions, such as the interaction of olefins with sulfuric acid or the various classes of adduct formation. Chemical fractionation is often but not always successful because of the complex nature of crude oil. This may result in unprovoked chemical reactions that have an adverse effect on the fractionation and the resulting data. Indeed, caution is advised when using methods that involve chemical separation of the constituents.

The order in which the several fractionation methods are used is determined not only by the nature and/or composition of the crude oil but also by the effectiveness of a particular process and its compatibility with the other separation procedures to be employed. Thus, although there are wide variations in the nature of crude oil, there have been many attempts to devise standard methods of crude oil fractionation. However, the various laboratories are inclined to adhere firmly to, and promote, their own particular methods. Recognition that no one particular method may satisfy all the requirements of crude oil fractionation is the first step in any fractionation study. This is due, in the main part, to the complexity of crude oil not only from the distribution of the hydrocarbon species but also from the distribution of the heteroatom (nitrogen, oxygen, and sulfur) species.

See also: Fractionation.

Fractionation

The composition of any feedstock or products, including those involved as alternative fuel sources, is an important aspect in determining the suitability of the feedstock for the process and the importance of the process in producing

the desirable products. In addition, the order in which the several fractionation methods are used is determined not only by the nature and/or composition of the feedstock (such as a complex material such as bio-oil) but also by the effectiveness of a particular process and the compatibility of the fractionation process with the other separation procedures to be employed. For example, rather than leaving the further processing of gaseous, liquid, or solid products to guesswork, determining the composition of the feedstock and the associated product before submitting the feedstock to a conversion process is a valuable asset in determining the suitability of the process.

The importance of chemical and physical properties is dependent upon the composition of the feedstock. In the strictest sense, feedstocks such as biomass and waste, are complex chemical mixtures which contain hydrocarbon derivatives and non-hydrocarbon derivatives that confer properties on the mixture that may not be reflected in the composition. Therefore, it is necessary to apply various test methods to petroleum and petroleum products to determine if the material is suitable for processing and (in the case of the products) for sale with a designated use in mind.

In fact, the processes that constitute gas cleaning operations are derived from the various gas cleaning options and may, in fact, be considered as the application of a series fractionation processes to the fractionation of a gas stream into a series of sub-fractions or products. Also, the order in which any one of the several fractionation methods are used is determined not only by the nature and/or composition of the feedstock or product(s) oil but also by the effectiveness of a particular process and its compatibility with the other separation procedures to be employed. Thus, although there are wide variations in the nature of feedstocks (especially biomass) for the production of alternative fuels, the recognition that no one particular method may satisfy all the requirements of the fractionation process is the first step in any fractionation study. This is due, in the main part, to the complexity of the feedstock not only from the distribution of the constituents of the feedstock species but also from the distribution of the heteroatom (nitrogen, oxygen, and sulfur) species and the occurrence of these species in the product(s).

See also: Bio-oil, Fractional Composition, Gas Cleaning, Gas Processing, Gas Treating.

Fractionation – Absorption Methods

Already used in gas cleaning processes, absorption methods offer fractionation method in the gas cleaning (gas processing industry).

Gas processing (gas refining) is a pertinent example of the application of fractionation methods to the determination of the composition of a gaseous feedstock or the distribution of gaseous products from a process.

Many chemical processes are available for processing or refining natural gas. However, there are many variables in the choice of process or the choice of refining sequence that dictate the choice of process or processes to be employed. In this choice, several factors must be considered: (i) the types and concentrations of contaminants in the gas, (ii) the degree of contaminant removal desired, (iii) the selectivity of acid gas removal required, (iv) the temperature, pressure, volume, and composition of the gas to be processed, (v) the carbon dioxide-hydrogen sulfide ratio in the gas, and (vi) the desirability of sulfur recovery due to process economics or environmental issues.

In addition to hydrogen sulfide and carbon dioxide, the gas stream may contain other contaminants, such as mercaptans (also called *thiols*, R-SH) and carbonyl sulfide (COS). In fact, the variation in the composition of the gases that require separation either before being assigned to further use requires a variation of separation types to ensure that specifications are met and the environment is protected. The presence of various constituents may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to separate large amounts of acid gases.

Method selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes separate both hydrogen sulfide and carbon dioxide from a gas stream while other methods may be designed to remove hydrogen sulfide only. It is important to consider the process method for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream.

Fractionation – Adsorption Methods

Separation by adsorption chromatography essentially commences with the preparation of a porous bed of finely divided solid, the adsorbent. The adsorbent is usually contained in an open tube (column chromatography); the sample is introduced at one end of the adsorbent bed and induced to flow through the bed by means of a suitable solvent. As the sample moves through the bed, the various components are held (adsorbed) to a greater or lesser extent depending on the chemical nature of the component. Thus, those molecules that are strongly adsorbed spend considerable time on the adsorbent surface rather than in the moving (solvent) phase, but components that are slightly adsorbed move through the bed comparatively rapidly.

It is essential that, before application of the adsorption technique to the feedstock, any insoluble material should be completely removed. The prior removal of an insoluble portion of the feedstock is essential insofar as the insoluble constituents may be irreversibly adsorbed on the adsorbent.

Careful monitoring of the experimental procedures and the nature of the adsorbent has been responsible for the successes achieved with this particular technique. Early procedures consisted of warming solutions of the feedstock with the adsorbent and subsequent filtration. This procedure has continued to the present day, and separation by adsorption is used commercially in plant operations in the form of clay treatment. In addition, the proportions of each fraction are subject to the ratio of adsorbent to the liquid feedstock.

It is also advisable, once a procedure using a specific adsorbent has been established, that the same type of adsorbent be employed for future fractionation since the ratio of the product fractions varies from adsorbent to adsorbent. It is also very necessary that the procedure be used with caution and that the method not only be reproducible but quantitative recoveries and reproducibility be guaranteed.

In summary, the variety of fractions isolated by these methods and the potential for the differences in composition of the fractions make it even more essential that the method is described accurately and that it is reproducible not only in any one laboratory but also between various laboratories.

Fractionation – Chemical Methods

Methods of fractionation using chemical reactants are entirely different in nature from the methods described in the related sections. Although several methods using chemical reactants have been applied to fractionation, methods such as adsorption, solvent treatment, and treatment with alkali are often applied to product purification as well as separation.

The method of chemical separation commonly applied to separate a feedstock into various fractions is treatment with sulfuric acid, but caution is advised because of the potential for the formation of complex sulfates and difficult-to-break emulsions. Obviously, the success of this fractionation method is feedstock dependent and, in conclusion, it would appear that the test be left more as a method of product cleaning for the process has been widely used in industry rather than as a method of separation of the various fractions.

Fractionation – Distillation Methods

Distillation is a means of separating chemical compounds (usually liquids) through differences in the vapor pressure of the various liquids.

Simple distillation is effective only when separating (under the conditions of the method) a volatile liquid from a nonvolatile substance or when separating liquid constituents that differ in boiling point. Thus, in the mixture, the components evaporate and the vapor has a composition determined by the chemical properties of the mixture. Distillation of a given component is possible, if the vapor has a higher proportion of the given component than the mixture. This is caused by the given component having a higher vapor pressure and a lower boiling point than the other components.

The equipment may affect separation by one of two main methods. First, the vapors given off by the heated mixture may consist of two liquids with significantly different boiling points. Thus, the vapor that is given off is in the vast majority of one or the other liquid, which after condensation and collection effects the separation. Second, fractional distillation may be necessary and is more effective at separating liquids that have similar boiling points. This method relies upon a gradient of temperatures existing in the condenser stage of the equipment. Often in this technique, a vertical condenser, or column, is used, and by removal of the distillation products that are liquid at different heights up the column, it is possible to separate liquids that have different boiling points. The greater the distance over which the temperature gradient in the condenser is applied leads to easier and more complete separation.

The basic idea behind fractional distillation is the same as simple distillation, only the process is repeated many times. If simple distillation was performed on a mixture of liquids with similar volatilities, the resulting distillate would be more concentrated in the more volatile compound than the original mixture, but it would still contain a significant amount of the higher boiling compound. If the distillate of this simple distillation was distilled again, the resulting distillate would again be even more concentrated in the lower boiling compound, but still a portion of the distillate would be the higher boiling compound. If this process is repeated several times, a fairly pure distillate will eventually result.

In fractional distillation, the vapors formed from the boiling mixture rise into the fractionating column where they condense on the column's packing. This condensation is tantamount to a single run of simple distillation; the condensate is more concentrated in the lower boiling compound than the mixture in the distillation flask. As vapors continue to rise through the column, the liquid that has condensed will vaporize. Each time this occurs, the resulting vapors are more and more concentrated in the more volatile substances. The length of the fractionating column and the material it is packed with impact the number of times the vapors will condense before passing into the condenser; the number of times the column will support this is referred to as the number of theoretical plates of the column.

The fractionating column supplies a temperature gradient over which distillation occurs. In an ideal situation, the temperature in the distillation flask would be equal to the boiling point of the mixture of liquids and the temperature at the top of the fractionating column would be equal to the boiling point of the lower boiling compound; all of the lower boiling compound would be distilled away before any of the higher boiling compound. In reality, fractions of the distillate must be collected because as the distillation proceeds, the concentration of the higher boiling compound in the distillate being collected steadily increases. Fractions of the distillate, which are collected over a small temperature range, will be essentially purified; several fractions should be collected as the temperature changes, and these portions of the distillate should be distilled again to amplify the purification that has already occurred.

Fractionation – Solvent Methods

Solvent methods achieve fractionation on the basis of (i) molecular weight and (ii) polarity. A common solvent separation process used involves solvent precipitation. The simplest application of solvent extraction consists of mixing the feedstock with a liquid, which results in the formation of two phases. This causes distribution of the feedstock constituents over the two phases: (i) the dissolved portion, which is the extract and (ii) the non-dissolved portion, which is the raffinate.

The list of compounds that have been suggested as selective solvents for the preferential extraction fractionation of the variety of feedstocks contains a large selection of different functional types. However, before any extraction process is attempted, it is necessary to consider the following criteria: (i) the differences in the solubility of the feedstock constituents in the solvent should be substantial, (ii) the solvent should be significantly less dense or denser than the product to be separated to allow easier countercurrent flow of the two phases, and (iii) separation of the solvent from the extracted material should be relatively easy. It may also be advantageous to consider other properties, such as viscosity, surface tension, and the like, as well as the optimal temperature for the extraction process.

There is also the option of reactive extraction in which the insoluble feedstock reacts with the solvent at high temperature (which will be dependent on the feedstock composition and properties, the contact time, and the pressure) to produce a soluble product.

Fuel Cell

A fuel cell is an electrochemical device that will efficiently convert diverse fuels directly into electricity without combustion, and they are key elements of a broad portfolio for building a competitive, secure, and sustainable clean energy economy. The fuel cell offers a broad range of benefits, including reduced greenhouse gas emissions; reduced oil consumption; expanded use of renewable power (through the use of hydrogen derived from renewable resources as a transportation fuel as well as for energy storage and transmission); highly efficient energy conversion; fuel flexibility (use of diverse, domestic fuels, including hydrogen, natural gas, biogas, and methanol); reduced air pollution, criteria pollutants, water use; and highly reliable grid support. Fuel cells also have numerous advantages that make them appealing for end users, including quiet operation, low maintenance needs, and high reliability. Because of their broad applicability and diverse uses, fuel cells can address critical challenges in all energy sectors: commercial, residential, industrial, and transportation.

A fuel cell and a battery are both electrochemical devices that convert chemical energy into electrical energy. The chemical reaction in a battery releases electrons that travel between the terminals and out as electricity. Moreover, when electricity is released from the battery, the battery's stored energy is being used up because the battery is a closed storage system. It can only produce so much energy before it dies and needs to be recharged or replaced. The fuel cell, on the other hand, is more of an energy converter than an energy storage device. Its chemical reaction converts hydrogen and oxygen into water and in the process produces electricity. A fuel cell will provide power as long as it is supplied with fuel. It does not run down or require recharging like a battery. A fuel cell can be refilled with hydrogen like filling an automobile gas tank.

Fuel Oil

Fuel oil is produced in a refinery but can also be produced from liquid produced from biomass.

No. 1 fuel oil is a petroleum distillate that is one of the most widely used of the fuel oil types. It is similar to kerosene and is used in burners where vaporization before burning is usually required and a clean flame is specified.

No. 1 fuel oil is used in atomizing burners that spray fuel into a combustion chamber where the tiny droplets burn while in suspension. It is also used as a carrier for pesticides, as a weed killer, as a mold release agent in the ceramic and pottery industry, and in the cleaning industry. It is found in asphalt coatings, enamels, paints, thinners, and varnishes. No. 1 fuel oil is a light petroleum distillate (straight-run kerosene) consisting primarily of hydrocarbons in the range C_9 - C_{16} . Fuel oil #1 is similar in composition to diesel fuel; the primary difference is in the additives.

See also: Refining.

No. 2 fuel oil, also called domestic heating oil or industrial heating oil, is a petroleum distillate that has properties similar to diesel fuel and heavy jet fuel. It is used in burners where complete vaporization is not required before burning. Domestic fuel oil is usually lower boiling and a straight-run product. It is used primarily for home heating. The industrial-grade industrial distillate is a cracked product or a blend of both and is used in smelting furnaces, ceramic kilns, and packaged boilers. No. 2 fuel oil is characterized by hydrocarbon chain lengths in the C_{11} - C_{20} range. The composition consists of aliphatic hydrocarbons (straight chain alkanes and cycloalkanes) (64%), 1-2% unsaturated hydrocarbons (alkenes) (1 to 2%), and aromatic hydrocarbons (including alkyl benzenes and 2-ring, 3-ring aromatics) (35%) but contains only low amounts of the polycyclic aromatic hydrocarbons (<5%).

No. 4 fuel oil is a light (relatively low boiling) industrial heating oil and is used where preheating is not required for handling or burning; there are two grades of No. 4 fuel oil, differing in safety (flash point) and flow (viscosity) properties. No. 5 fuel oil is a heavy (relatively high boiling) industrial fuel oil which requires preheating before burning.

No. 6 fuel oil (also called Bunker C oil or residual fuel oil) is the residuum from crude oil after naphtha-gasoline, No. 1 fuel oil, and No. 2 fuel oil have been removed. No. 6 fuel oil can be blended directly to heavy fuel oil or made into asphalt. Residual fuel oil is more complex in composition and impurities than distillate fuels. Limited data are available on the composition of No. 6 fuel oil. Polycyclic aromatic hydrocarbons (including the alkylated derivatives) and metal-containing constituents are components of No. 6 fuel oil. Preheating is always required for burning this oil.

See: Refining.

Fuels

A fuel is a substance that may be burned in air (or any other oxidant-containing substance) (Table F-7), and the reaction (with the oxidant, for the most part, oxygen) is rapid so that heat and light are emitted in the form of a sustained flame.

Table F-7 General description of fuel types.

Fuel type	Description
Gas	Natural gas, oil derivatives (LPG), acetylene, manufactured gas from coal or oil residue, and biogas from manure or sewage.
Liquid	Crude-oil derivatives (gasoline, diesel, fuel oil), alcohols, ethers, esters, but also liquefied petroleum gas (LPG) at low temperatures.
Solid	Coal (mineral), charcoal (from wood) and biomass (wood, dung), but also waxes, metals, and nonmetals (for example, sulfur ignites easily, producing a pungent blue flame).
	Also, aluminum particles are used in the rocket boosters for heavy-lift payloads.

Fuels are mostly used as convenient energy stores because of their high specific energy release when burnt with omnipresent ambient air (or other specific oxidizer). The same fuel substance may be also used as a feedstock in chemical synthesis (e.g., polymers from petroleum), lubricants, paints (who has never used a coal chunk to draw), and so on, but these uses are minority. Primary fuels (natural fuels) may be difficult to find, and secondary fuels (artificial fuels) may be difficult to manufacture but fuels are easy to store, transport, and use, with the only nuisance of safety (uncontrolled combustion) and pollution (toxic emissions during storage and when burnt).

Although the chemical reactions of wood in air, animal-fat in air, coal in air, natural gas in air (approximated by $\text{CH}_4/\text{O}_2/\text{N}_2$), hydrogen in oxygen (H_2/O_2), silicon in oxygen (Si/O_2), sodium in chlorine ($\text{Na(s)}/\text{Cl}_2(\text{g})$), zirconium powder in carbon dioxide (Zr/CO_2), and nitrocellulose $[-(\text{C}_6\text{H}_{10}\text{O}_5)_n-$ with $n=300$ to $.2000$) in any medium are all of the same chemical type (self-propagating highly-exothermic re-dox reactions, i.e., combustion processes). Usually, the terms words and combustion only refer to easily flammable substances in air (air is the oxidizer or oxidant that is needed by a fuel to burn).

Oxygen in the air is the basic oxidant for fuels: nitrogen is basically inert, although it combines endothermically with oxygen at high temperatures to get the unwanted nitrogen oxide (NO_x) pollutants. Oxygen is readily available from the atmosphere of the Earth.

Fuels from Biomass

The production of fuels from biomass (biofuels) to replace crude oil and natural gas is in active development, focusing on the use of cheap organic matter (usually cellulose, agricultural, and sewage waste) in the efficient production of liquid and gas biofuels which yield high net energy gain.

The carbon in biofuels was recently extracted from atmospheric carbon dioxide by growing plants, so burning it does not result in a net increase of carbon dioxide in the atmosphere of the Earth. As a result, biofuels are seen by many as a way to reduce the amount of carbon dioxide released into the atmosphere by using them to replace non-renewable sources of energy.

Gasoline is a blend of hydrocarbon derivatives with some contaminants, including sulfur, nitrogen, oxygen, and certain metals. Ethanol and methanol are biofuels that provide an alternative to gasoline. Bioethanol is a fuel produced by processing familiar and renewable crops such as cereals, sugar beet, and maize using natural fermentation. Blended with petrol at 10%, bioethanol can be used in vehicles without the need to change fuel or engine specifications.

Biofuels are important because they replace crude oil fuels and can be used to fuel vehicles, but can also fuel engines or fuel cells for electricity generation. Biofuels are generally more environmentally benign than traditional fuels and are further defined as being renewable, meaning that the feedstock used to make a particular biofuel can be replenished at a rate equal to or faster than the rate at which the biofuel is consumed.

Fuels from Crops

Crops have essentially many functions and benefit particularly for the human animal! Their products are not only used as a primary source of human foods and animal feed, but also as a source of timber, fibers and biomass energy. In addition, crops also have an essential function to maintain ecological systems and natural environment.

Grain crops include corn, wheat, rice, barley, and other cereals. The seeds of these plants are typified by their high starch content that can be hydrolyzed to fermentable sugars for ethanol production. Sugar crops, including sugar cane, beet, and sweet sorghum, are preferable to starch crops to the extent that sucrose is more readily hydrolyzed to fermentable sugars. However, sugar cane production is restricted to warm climates, and requires both high-quality land and irrigation. Sweet sorghum has considerable advantages over sugar cane as an energy crop. It can grow in a variety of soils and climatic conditions, and its production costs have been estimated to be just over half those for sugar cane.

Most of crop production is used as foods, and the concern is that biofuels can consume these crops. However, more crops are being cultivated for non-food use such as pharmaceutical and nutritional products, chemical derivative products such as adhesive, paints, polymer, plastics and industrial oils in forms of bio diesel, ethanol, two cycle oils, transmission fluids, and lubricants.

Many efforts have been carried out to grow crops for food production in order to strengthen food security, and to alleviate the hunger and poverty particularly in developing countries. However, attention should also be directed toward cultivation of crops for non-food use since, in some cases, cultivating for non-food products may provide a higher value added, a higher profit, and higher income, i.e., an increase in farm income. The hunger and poverty problems do not essentially rely on the incapability of individuals to produce of foods by themselves, but depend on the capability of individuals to access foods by their income.

Energy crops are plants grown specifically for use as a fuel. Although growing crops for fuel dates from medieval times, in their modern form, energy crops are the most recent and innovative renewable energy option. Energy crops are important as a renewable energy technology because their use will produce a variety of economic, environmental, and energy benefits.

Wood is the oldest fuel known to man. Burning wood rather than fossil fuels can reduce the carbon dioxide emissions responsible for global climate change. Wood fuel is carbon dioxide neutral. It gives off only as much carbon dioxide when burnt as it stores during its lifetime. In addition, wood fuel has low levels of sulfur, a chemical that contributes to acid rain.

Biomass like wood can be used to produce electricity by direct combustion or gasification. It includes short rotation coppice and forestry waste. Biomass has some attractions as a fuel over some other renewable energy sources since it is not an intermittent resource – it can be supplied on a continuous basis to fuel base load plants.

Regularly coppiced plantations will actually absorb more carbon dioxide than mature trees – since carbon dioxide absorption slows once a tree has grown. Growing crops for fuel, particularly wood coppice, offers very promising developments for the future. Short rotation arable coppicing, using fast-growing willows, is currently seen as an important source of fuel for electricity generation. The overall process involves several stages – growing over two or three years, cutting and converting to wood chip, storage and drying, and transporting to a power plant for combustion. And the combustion process can be very efficient, given the development of advanced co-generation techniques.

Energy crop fuel contains almost no sulfur and has significantly less nitrogen than fossil fuels; therefore, reductions in sulfur oxide and nitrogen oxide pollutants causing acid rain and smog may be realized.

Burning fossil fuels removes carbon that is stored underground and transfers it to the atmosphere. Burning energy crops, on the other hand, releases carbon dioxide, but as their growth requires carbon dioxide, there is no net release of carbon into the atmosphere, i.e., it creates a closed carbon cycle. Furthermore, where energy crops are gasified,

there is a net reduction of carbon dioxide. In addition, substantial quantities of carbon can be captured in the soil through energy crop root structures, creating a net carbon sink.

An additional environmental benefit is in water quality, as energy crop fuel contains less mercury than coal.

Also, growing energy crops on agricultural land that might otherwise be converted to residential or industrial use will reduce erosion/chemical runoff and enhance wildlife habitat. This will give energy producers, and consumers will have available a renewable energy option with uniquely desirable characteristics. For example, energy crops differ from other sources of renewable energy in virtue of the fact that they can be grown to meet the needs of the market whereas other renewable resources (for example, wind and wave power) must be harnessed where and when they occur.

Moreover, the security of energy supply will be significantly enhanced for many crop-growing countries. Energy crop production and use could reduce dependency on imported oil, although complete energy independence must, for the time, remain a possible future event.

Fuels from Waste

Many fuels can be derived from waste such as (i) waste vegetable oil, (ii) organic waste, and (iii) used tires. Waste vegetable oil currently used to produce biodiesel consists mostly of rapeseed oil; the transesterification process of rapeseed oil produces RME (rape methyl ester). However, there is no guarantee of the purity of the oil as a proportion will be oil produced from other crops such as sunflower oil or olive oil.

Anaerobic digestion is the use of bacteria to decompose organic matter in the absence of oxygen to produce gases. These gases are produced from organic wastes such as livestock manure and food processing waste. The end product is a medium heating value biogas mixture (usually 60% methane, 40% carbon dioxide) and a mixture of solid and liquid fertilizer. Because anaerobic digestion does not produce anymore carbon dioxide than would normally be produced from the wastes' natural decomposition, it is said to be carbon neutral.

There are a number of various designs of digester, but the same process is usually followed. The digester itself comprises of an airtight container with an expandable cover to allow gas buildup before siphoning. Waste is then pumped regularly (typically, once a day) into the digester, remaining there for between 10 and 40 days. The temperature inside the digester must be between 30 and 70 degrees Celsius.

Any mixture of organic waste materials may be used such as animal and human sewage, crop residues, newspaper, abattoir waste, food processing, and agricultural waste. The availability of different feedstocks varies due to different harvest times and also the time of year (e.g., manure collection easier when animals are indoors for winter). Therefore, feedstock mixtures may vary at different times of the year in order to keep the digester active for continuous production.

Since the product in this process is a gas, then generally, this fuel is more suited to electricity generation as opposed to use as a transport fuel. The changes to current infrastructure that would be required to accommodate such a fuel would be difficult at best, though some of the infrastructure does exist due to the use of compressed natural gas (CNG).

Used tire pyrolysis is another process which produces gases, small quantities of liquid, and a solid residue containing carbon and ash. The gases produced in the process can then be used to provide the heating energy for continuing the process. The tire pyrolysis process essentially returns the high heating value of the rubber and oils that were initially used in the manufacture of the tires. By carefully controlling the temperature, pressure, and oxygen level, more pyrolysis oil and charcoal are encouraged. This pyrolysis oil can then be used as a replacement diesel fuel.

A significant number and variety of organic wastes are combusted in energy recovery systems including municipal solid waste (MSW), various forms of refuse-derived fuel produced from municipal solid waste as well as a broad range of other specific specialty wastes. The practice of incinerating waste has become increasingly prevalent in order to accomplish disposal in a cost-effective, environmentally sensitive manner. Combustion of such wastes reduces the volume of material which must be sent to a landfill, reduces the airborne emissions resulting from plant operations and landfill operations, and permits some economic benefit through energy recovery.

The technologies used to combust wastes depend on the form and location of components to be burned. The issues associated with energy generation from waste include fuel composition characteristics, combustion characteristics, formation and control of airborne emissions including both criteria pollutants and air toxics, such as trace metals; and the characteristics of bottom and fly ash generated from waste combustion.

The concept of the incineration of domestic and industrial waste to gaseous fuels is one of the first suggestions from the disposal of waste and the generation of energy. With this in mind, waste incineration has been, and continues to be, practiced in many parts of the world. In fact, co-combustion of waste in (large and efficient) coal-fired power plants is an especially attractive option because of the high conversion efficiency of these plants. However, there are issues that need attention, and while it is not intended here to use the following comments to be a critique of waste incineration, here are lessons to be learned and changes to be made in this manner of waste removal.

Although not in keeping with the main context of this text, i.e., the production of fuels, the incineration of wastes is worthy of mention insofar as waste combustion (although the main goal of incineration is volume reduction with the sterilization of the waste as a significant side-effect) can be a source of energy but, generally. Thus, the incineration process may also be used to produce steam and electricity. However, as the moisture content of the waste increases, a self-sustaining combustion process is not possible. Nevertheless, domestic waste and industrial waste are feedstocks for incinerators.

Incineration is recognized as a waste treatment technology for disposal of the organic constituents of the waste. Incineration and other high-temperature waste treatment systems convert the waste into ash, flue gas, particulate matter, and heat, which can in turn be used to generate electricity. The flue gases are cleaned for pollutants before it is dispersed in the atmosphere. Furthermore, incineration with energy recovery is one of several waste-to-energy technologies such as gasification and anaerobic digestion.

Modern incinerators reduce the volume of the original waste by 95-96%, depending upon the composition and degree of recovery of materials such as metals from the ash for recycling. While incineration does not replace land-filling, it does reduce the necessary volume significantly. In fact, incineration has particularly strong benefits for the treatment of certain waste types in niche areas such as clinical wastes and certain hazardous wastes where pathogens and toxins can be destroyed by high temperatures.

Incineration is not a complete method of disposal; the main advantage of the process is that a residue is produced which is substantially reduced in volume and may be relatively inert. In addition, the efficiency of an incinerator is, on occasion, due to excessive throughput or choice of operating parameters that are less than desired. For example, the operating temperature inside the plant should be at the specified temperature (usually on the order of 850°C, 1,560°F) to reduce the possible effects of the most dangerous air pollutants and the production of dioxins. A lower than specified combustion temperature implies incomplete incineration, leaving part of the waste in the ashes and other combustion residues. Furthermore, the exhaust gases may be unnecessarily polluting because of the low combustion temperature and the by-products of such combustion may be sent to an unprotected landfill for disposal.

Fuels from Wood

Energy from wood can come in several forms. There are three options currently available for producing heat from wood in the form of (i) logs, (ii) woodchips, and (iii) reconstituted fuels such as pellets and briquettes. Other options which are at the research stage include liquid fuels produced from wood and bales of compressed forest residues.

Logs and wood chips can come from forest thinnings, coppicing, tree-surgery, and pruning operations – even whole trees can be chipped to provide fuel. Woodchips can also be produced from fast-growing varieties of willow and poplar which are cultivated by Short Rotation Coppicing specifically to produce energy. On the other hand, wood pellets are made from highly compressed dry wood shavings and sawdust, usually from sawmilling and joinery operations.

Logs and wood chips can come from forest thinnings, coppicing, tree-surgery, and pruning operations – even whole trees can be chipped to provide fuel. Woodchips can also be produced from fast-growing varieties of willow and poplar which are cultivated by Short Rotation Coppicing specifically to produce energy. On the other hand,

wood pellets are made from highly compressed dry wood shavings and sawdust, usually from sawmilling and joinery operations.

The main processes for the conversion of wood to fuel are, after drying and resizing in which the wood is cut and split in sizes that are easy to transport or before being burned or used as raw material in one of the following processes: (i) carbonization, which is the process of burning wood or biomass in the absence of air breaks it down into liquids, gases, and charcoal, (ii) gasification, which is the process in which solid biomass fuels (e.g., wood, charcoal) are broken down by the use of heat to produce a combustible gas, known as producer gas, (iii) densification, which is used to overcome the bulky nature, low thermal efficiency, and smoke emission of wood and agriculture residues; these can be processed to produce smokeless briquettes with or without binders, (iv) liquid fuel production: for example, ethanol production by alcohol by hydrolysis or anaerobic digestion; liquid fuels can be produced from several biomass types such as wood pulp residues (black liquor), sugarcane, and cassava, and (v) combustion, since biomass fuels can also be used for power generation and/or heat production by direct combustion, either in its primary form or after one or more of the above-mentioned transformation processes.

Generally, biomass fuels such as wood are consumed by direct combustion in their primary form after drying and resizing, or in the form of charcoal. New conversion technologies such as gasification and anaerobic digestion have been developed to provide renewable fuels and to match biomass resources with modern end-use devices. However, as of yet, these technologies are not widely used, so also in the near future, wood energy conversion will consist mainly of resizing, drying, and charcoal production. Nevertheless, in recent years, there has been increasing use of wood and other biomass for energy conversion in modern applications, such as combined heat and power generation (CHP) and co-generation.

Wood fuels consist of three main commodities: fuel wood, charcoal, and black liquor. Fuel wood and charcoal are traditional forest products derived from the forest, trees outside forests, wood processing industries, and recycled wooden products from society. Black liquors are by-products of the pulp and paper industry.

Wood can be used to make both liquid and gaseous fuels. When wood is heated in the absence of air, or with a reduced air supply, it is possible to produce a liquid fuel which can be used in a similar way to conventional oil fuels. It can be used to run internal combustion engines in vehicles or generators. The gas produced from wood is a mixture of hydrogen and carbon monoxide which is similar to the coal gas which was made before the arrival of natural gas from the North Sea. This wood gas can be used in internal combustion engines or in gas turbines which can be used to power generators. Although the liquid fuels are rarely produced from wood at present, wood gas is important in other countries for producing electricity in more remote areas.

Gasification technology is an attractive route for the production of fuel gases from biomass. By gasification, solid biomass is converted into a combustible gas mixture normally called producer gas consisting primarily of hydrogen (H_2) and carbon monoxide (CO), with lesser amounts of carbon dioxide (CO_2), water (H_2O), methane (CH_4), and higher hydrocarbon derivatives (C_xH_y), as well as nitrogen (N_2) and particulates.

The gasification is carried out at elevated temperatures, 500°C and 1,500°C (930 to 2730°F) and at atmospheric or elevated pressures. The process involves conversion of biomass, which is carried out in absence of air or with less air than the stoichiometric requirement of air for complete combustion. Partial combustion produces carbon monoxide as well as hydrogen which are both combustible gases. Solid biomass fuels, which are usually inconvenient and have low efficiency of utilization, can be converted into gaseous fuel. The energy in producer gas is 70% to 80% of the energy originally stored in the biomass. The producer gas can serve in different ways: it can be burned directly to produce heat or used as a fuel for gas engines and gas turbines to generate electricity; in addition, it can also be used as a feedstock for the production of synthesis gas in the production of chemicals, e.g., methanol.

Fuel Wood

Fuel wood (fuelwood, firewood) is wood used for conversion to some form of energy, primarily for residential use. Fuel wood usually relates to timber or trees unsuitable for building or construction. Firewood is a renewable resource provided the consumption rate is controlled to sustainable levels. The shortage of suitable firewood in some places has seen local populations damaging huge tracts of bush, thus leading to further desertification.

Fuel wood (i.e., wood itself) is the most common solid fuel and continues to be widely used as a major source of energy for households, especially in developing countries. Charcoal is also increasingly used in many African countries by urban dwellers, as a result of a relentless process of migration of people from rural areas toward urban centers. The major energy end-use in households is cooking, and approximately 86% of fuel wood consumed in urban households in India is for this purpose, while the rest is mostly used for water heating. In Africa, more than 86% of total wood fuels consumption was attributed to the household sector in 1994. Dependence on wood fuels to meet household energy needs is especially high in most of sub-Saharan Africa, where 90 to 98% of residential energy consumption is met from this source.

When used as a solid fuel, some fuel wood (firewood) is harvested in woodlots managed for that purpose, but in heavily wooded areas, it is more usually harvested as a by-product of natural forests. Deadfall that has not started to rot is preferred, since it is already partly seasoned. Standing dead timber is considered better still, as it is both seasoned, and has less rot. Harvesting this form of timber reduces the speed and intensity of bush fires. Harvesting timber for firewood is normally carried out by hand with chainsaws. Thus, longer pieces – requiring less manual labor and less chainsaw fuel – are less expensive (but the user must ensure that the lengths will fit in the firebox!) Prices also vary considerably with the distance from wood lots, and quality of the wood.

In places with high fuel wood and charcoal consumption (due to high population density with low income and/or severe climatic conditions) and weak supply sources, strong pressures are put on existing tree resources, and deforestation and devegetation problems remain a matter of great concern. In addition, urbanization and economic development are bringing changes to the consumption patterns in developing countries, which in turn are leading to major changes in the household energy sector.

In developed countries, heat production by households also remains the major use of fuel wood. For instance, in the European Union, wood fuels account for around 60% of the total wood energy consumed, although their utilization as an industrial energy source for electricity and heat generation is increasing, as a result of new energy policies enacted in most countries to comply with climate change mitigation programs.

Fuel Wood – Selection and Preparation

As with any fire, burning wood fuel creates numerous by-products, some of which may be useful (heat and steam), and others that are undesirable, irritating, or dangerous. However, before fuel wood is used, there are several processes that are necessary for application:

Firewood can be sold by weight. Freshly cut (green) wood can contain from 40 to 60% moisture by weight, whereas properly seasoned wood contains only 15 to 20%. Select the driest wood when buying by weight. Green wood will shrink approximately 8% in volume when properly seasoned.

Wood should be dried as much as possible before burning. Properly seasoned wood has approximately 7,700 Btu per pound maximum usable energy per pound versus only approximately 5,000 Btu per pound available from green wood. Wood must be properly stacked for satisfactory drying. The greater the surface area exposed to air, the more rapid the drying. Therefore, stack wood loosely and keep it off moist ground. The stack should be located in an open area for good air circulation – avoid stacking in wood lots for seasoning.

Fuel Wood – Use

Cellulose and hemicelluloses form mainly volatile products on heating due to the thermal cleavage of the sugar units. The lignin forms mainly char since it is not readily cleaved to lower molecular weight fragments. The progressive increase in the pyrolysis temperature of the wood led to the release of the volatiles, thus forming a solid residue that is different chemically from the original starting material. Cellulose and hemicelluloses initially break into

compounds of lower molecular weight. This forms activated cellulose which decomposes by two competitive reactions: one forming volatiles (anhydrosugars) and the other char and gases. The thermal degradation of the activated cellulose and hemicelluloses to form volatiles and char can be divided into categories depending on the reaction temperature. Within a fire, all these reactions take place concurrently and consecutively. Gaseous emissions are predominantly a product of pyrolytic cracking of the fuel. If flames are present, fire temperatures are high, and more oxygen is available from thermally induced convection.

See also: Charcoal, Wood.

Functional Group

One of the issues that arise when dealing with alternative fuels from biomass (e.g., bio-oil) is the presence of functional groups in the organic product(s). The presence of functional group not only affects the properties of the bio-oil but also affects the selection of the appropriate process required for the conversion of the bio-oil to useful products such as fuels.

A functional group is the part of an organic molecule which contains atoms other than carbon and hydrogen, or which contain bonds other than a carbon-carbon single bond (C-C) and a carbon-hydrogen bond (C-H). Some of the most common functional groups in organic chemistry are alkenes, alkynes, aromatics, nitriles, amines, amides, nitro compounds, alcohols, phenols, ethers, aldehydes, ketones, carboxylic acids, acid chlorides, acid anhydrides, esters, alkyl halides, thiols, and thioethers.

Functional groups are attached to the carbon backbone of organic molecules. They determine the characteristics and chemical reactivity of molecules. Functional groups are far less stable than the carbon backbone and are likely to participate in chemical reactions. The same functional group will undergo the same or similar chemical reaction(s) regardless of the size of the molecule. However, its relative reactivity can be modified by nearby functional groups.

The non-hydrogen atoms of functional groups are always associated with each other and with the rest of the molecule by covalent bonds. When the group of atoms is associated with the rest of the molecule primarily by ionic forces, the group is referred to more properly as a polyatomic ion or complex ion.

Compounds that contain carbon-oxygen single bonds (C-O bonds) each possess differing reactivity based upon the location and hybridization of the carbon-oxygen single bond, owing to the electron-withdrawing effect of sp^2 hybridized oxygen and the donating effects of sp^3 hybridized oxygen. Compounds that contain nitrogen in this category may contain C-O bonds, such as in the case of amides.

Thus, a functional group is any atom or collection of atoms that is capable of reacting with a reactive species to produce a product and is also capable of affecting the properties of the original non-functional molecule in which the group occurs. Some of the most common functional groups in organic chemicals are (i) the double bond of alkene derivatives, $R_1C=CR_2$, (ii) the triple bond of alkyne derivatives, $R_1C\equiv CR_2$, (iii) the aromatic ring in aromatic derivatives such as in benzene derivatives and including the ring systems in condensed-ring aromatic derivative, (iv) the carbon-nitrogen function in nitrile derivatives, $RC\equiv N$, (v) the carbon-nitrogen function in amine derivatives RNH_2 , R_1NHR_2 , and $R_1NH(R_3)R_2$, (vi) the oxygen-carbon-nitrogen function in amide derivatives ($RC(=O)NH_2$), (vii) the nitrogen-oxygen function in nitro compounds, RNO_2 , (viii) the oxygen-hydrogen function in alcohol derivatives, ROH , (ix) the oxygen-hydrogen function in phenol derivatives, $ArOH$, (x) the carbon-oxygen-carbon function in ether derivatives, R_1OR_2 , (xi) the carbon-oxygen double bond in aldehyde derivatives, $RCH=O$, (xii) the carbon-oxygen double bond in ketone derivatives, R_1COR_2 , (xiii) the carbon-oxygen double bond and oxygen-hydrogen bond in carboxylic acid derivatives, RCO_2H , (xiv) the carbon-oxygen double bond and oxygen-chloride bond in acid chloride derivatives, $RCOCl$, (xv) the carbon-oxygen-carbon bond in acid anhydride derivatives, $R_1CO-O-COR_2$, (xvi) the carbon-oxygen-carbon bond in ester derivatives, R_1COOR_2 , (xvii) the carbon-halogen bond in alkyl halide derivatives, RX , where X is a halogen, (xviii) the sulfur-hydrogen bond in thiol derivatives, RSH , and (xix) the carbon-sulfur-carbon bond in thioether derivatives R_1SR_2 . In each of the aforementioned examples, R_1 and R_2 are alkyl groups (the same or different) and Ar is a phenyl group or other aromatic group.

Table F-1 General properties of functional group compounds.

Group	Polarity	Volatility/melting point/boiling point	Soluble in water	Acid-base behavior	Common compounds
Alkanes C_nH_{2n+2}	Non-polar	Very volatile, smaller molecules are gases Boiling point increases with size due to increased dispersion forces and larger mass	No	None	Methane, propane, butane, octane, and higher molecular weight hydrocarbons, including wax
Alkenes/Alkynes C_nH_{2n}/C_nH_{2n-2}	Non-polar	Have similar b.p. to alkanes w/ same # of carbons but a few degrees lower since they have fewer electrons = less dispersion forces	No	None	
Halo-alkanes RX	Slightly Polar – non-polar	Most halo-alkanes are liquids at room temperature Only CH_3Cl , CH_3Br and CH_3CH_2Cl are gasses Dispersion forces are more important than dipole-dipole forces B.P. decreases with # of substituents since temporary dipole is stronger for long chains and attractions are more effective when molecules can pack closely	Slightly	None	Polyvinyl chloride Chlorofluorocarbons Teflon
Alcohols ROH	Polar bond capable of H-bonds	Volatile when pure but often mixed w/ H_2O Higher boiling points than alkanes b/c of hydrogen bonding Volatility and B.P. increase as length of chain increases	Yes, decreases w/ length of carbon chain	Weakly acidic and basic (amphoteric) like water b/c of $-OH$	Ethanol, isopropyl alcohol, menthol
Ethers ROR	Polar bonds, no H-bonds	Volatile Lower boiling points than alcohols b/c no hydrogen bonding			First anesthetic – diethyl ether
Amines RNH_2 or R_2NH or R_3N	Polar bonds, capable of H-bonds	Low volatility High boiling points b/c of H-bonding	Yes	Basic b/c of lone pair, $R-NH_2$ even more basic than NH_3	Amino acids Ammonia

(Continued)

Table F-1 General properties of functional group compounds. (*Continued*)

Group	Polarity	Volatility/melting point/boiling point	Soluble in water	Acid-base behavior	Common compounds
Aldehydes RCHO 	Polar carbonyl group (C=O) H-bond can form between carbonyl and water	B.P. is higher than that of similarly sized alkanes b/c of dipole-dipole forces. B.P. is lower than alcohols since dipole-dipole forces are weaker than H-bonds. B.P. increase with size of carbon chain	Yes, decreases w/ length of carbon chain	Carbonyl can act as a base	Formaldehyde
Ketones RCOR 	Polar carbonyl group (C=O) H-bond can form between carbonyl and water	See aldehydes	Yes, decreases w/ length of carbon chain	Carbonyl can act as a base	Acetone (nail polish remover)
Carboxylic Acids RCOOH 	Polar, capable of hydrogen bonds	Low volatility Higher boiling points b/c of hydrogen bonding	Yes decreases w/ length of carbon chain	Acid Methanoic is stronger than ethanoic b/c of R group.	Acetic acid – vinegar
Esters RCOOR 	Polar, no H-bonds H-bond can form between carbonyl and water	More volatility than carboxylic acids and lower boiling points b/c can't H-bond Liquids at room temp for smaller molecules	Small esters: yes, solubility decreases w/ size of chain		Polyesters Fatty acids
Amides 	Polar, amine can hydrogen bond	High m.p. b/c of hydrogen bonding Amides are liquids or solids at room temp	Yes	Amine part of amide is basic	Proteins Polypeptides Nylon

Fungi

A fungus (plural: fungi) is any member of the group of eukaryotic organisms that includes microorganisms such as yeasts and molds, as well as the more familiar mushrooms.

Fungi are non-photosynthetic organisms and frequently possess a filamentous structure. Some fungi are as simple as the microscopic unicellular yeasts, whereas other fungi form large, intricate toadstools. The microscopic filamentous structures of fungi generally are much larger than bacteria and usually are 5-10 microns in width. Fungi are aerobic (oxygen-requiring) organisms and generally can thrive in more acidic media than can bacteria. They are also more tolerant of higher concentrations of heavy metal ions than are bacteria.

Perhaps the most important function of fungi in the environment is the breakdown of cellulose in wood and other plant materials. To accomplish this, fungal cells secrete a biological catalyst (enzyme) called cellulase. This enzyme

breaks insoluble cellulose down to soluble carbohydrates that can be absorbed by the fungal cell. Because it acts outside the organism, it is called an extracellular enzyme or exoenzyme.

Although fungi do not grow well in water, they play an important role in determining the composition of natural waters and wastewaters because of the large amount of their decomposition products that enter water. An example of such a product is humic material, which interacts with hydrogen ions and metals.

Fusion Energy

Fusion is a form of nuclear energy that can be used to produce electricity in large base load power plants. The basic nuclear processes involved occur at the opposite end of the spectrum of atomic masses than fission. Specifically, fission involves the splitting of heavy nuclei such as uranium-235 (^{235}U). Fusion involves the merging (i.e., the fusing) of light elements, mainly hydrogen (H , ^1H) and the hydrogen isotopes deuterium (D , ^2H) and tritium (T , ^3H).

There are three main advantages of fusion power: (i) fuel reserves, (ii) environmental impact, and (iii) safety.

In terms of the fuel reserves, there are two main reactions of interest that occur at a fast enough rate to produce electricity. These involve pure deuterium and an equal mix of deuterium and tritium. Deuterium occurs naturally in ocean water. There is 1 atom of deuterium for every 6,700 atoms of hydrogen, and deuterium can be easily extracted at a low cost. If all the deuterium in the ocean were used to power fusion reactors utilizing a standard steam cycle, there would be enough energy generated to power the earth for approximately 2 billion years (2×10^9 years) at the present rate of total world energy consumption.

The deuterium–tritium (D-T , $^2\text{H-}^3\text{H}$) reaction produces more energy than a pure deuterium (D-D , $^2\text{H-}^2\text{H}$) reaction. However, the main advantage is that deuterium–tritium reactions occur at a faster rate, thereby making it easier to build such a reactor. Consequently, all first generation fusion reactors will use deuterium–tritium. In terms of reserves, the multi-billion years of deuterium applies to deuterium–tritium as well as deuterium–deuterium reactors. However, since tritium is a radioactive isotope with a half-life on the order of 12 years, there is no natural tritium to be found on earth. Instead, tritium is obtained by breeding with the lithium isotope lithium-6 (^6Li) which is one of the components in the fusion blanket.

The next advantage is the environmental impact of fusion. Fusion reactions produce no carbon dioxide or other greenhouse emissions. Fusion reactions also do not emit any other harmful chemicals into the atmosphere. The main end product of the fusion reaction is the harmless, inert gas helium (He). The biggest environmental issue in fusion is that one by-product of both the deuterium–deuterium and the deuterium–tritium reaction is a high-energy neutron. These neutrons are captured in the fusion blanket so they pose no threat to the public. However, as they pass through structural material on their way to the blanket, the neutrons cause the structure to become activated. Even so, this radioactive structural material has a short half-life so that the storage time required once it is removed is also short, on the order of 100 years. Overall, the entire environmental situation, fusion, is an attractive option.

The last major advantage involves safety. Here, since fusion is a nuclear process, there is concern related to the possibility of a radioactive meltdown. The basic laws of physics governing fusion reactions make this an unlikely (if not impossible) event. Specifically, in a fission reactor, the entire energy content corresponding to several years of power production is stored within the reactor core at any instant of time. It is this huge energy content that makes a meltdown possible. A fusion reactor does not depend on maintaining a chain reaction in a large sitting mass of fuel. Instead, fuel must be constantly fed into the reactor at a rate allowing it to be consumed as needed. The end result is that at any instant of time, the mass of fuel in a fusion reactor is small, perhaps corresponding to the weight of several postage stamps. It is this small instantaneous mass of fuel that makes a meltdown impossible in a fusion reactor.

Gamma Decay

Gamma decay (γ -decay) is a type of radioactive decay that an excited nucleus (A^*) can undergo. In contrast to alpha decay and beta decay, no particles are ejected from the nucleus when it undergoes this type of decay, but, instead, a high energy form of electromagnetic radiation – a gamma ray photon (γ) – is released leaving an unexcited nucleus (A).

Gamma rays are simply photons that have extremely high energies which are highly ionizing. Gamma radiation is unique in the sense that undergoing gamma decay does not change the structure or composition of the atom but does change the energy of the atom since the gamma ray carries no charge nor does it have an associated mass. In order for a nucleus to undergo gamma decay, it must be in some sort of excited energetic state.

Protons and neutrons are located in discrete energy states within the nucleus, not too different from the excited states that the electrons can occupy in atoms. If a proton or a neutron in nucleus is converted to an excited state – typically after alpha decay or beta decay – the new daughter nucleus must somehow release energy to allow the proton or neutron to relax back down to ground state. When the nucleon makes this transition from a high to a low energy state, a gamma photon is emitted. The general equation that represents this process is:

In this equation, A^* is the excited atom, A is a relaxed state of the initial excited atom, and γ is the released gamma ray photon.

The number of protons and neutrons in the nucleus does not change in this process, so the parent and daughter atoms are the same chemical element. In the gamma decay of a nucleus, the emitted photon and recoiling nucleus each have a well-defined energy after the decay. The characteristic energy is divided between only two particles.

Both uranium-238 (^{238}U) and uranium-235 (^{235}U) that are used as fuel for nuclear power plants undergo both alpha and gamma decays when used. Immediately following the fission process, gamma rays are released, resulting in high levels of radiation present around the reactor.

Gas Analysis

The only special features characterizing the sampling of gas stream the potential for the separation of liquid phase material when the ambient conditions change, and this effect can be reversed by restoring the original conditions.

Despite the great value of analytical procedures, however, many empirical tests relating to chemical and physical characteristics are carried out, either because they are more convenient, or more accurate, than determinations dependent upon analysis. Currently, the preferred method for the analysis of a gas stream is gas chromatography (for example, ASTM D2163) which will allow identification and measurement of the main components and traces, but it should be noted that gas chromatography is not entirely satisfactory for determining traces of higher boiling hydrocarbon derivatives.

Mass spectrometry (ASTM D2650) is also suitable for analysis of crude oil gases, but is not likely to be used if the chromatographic apparatus is already available. Of the other spectroscopic techniques, infrared and ultra-violet absorption may be applied to gas analysis for some specialized applications. Gas chromatography has also largely supplanted chemical absorption methods of analysis, but again these may have some limited specialized application.

Satisfactory combustion of hydrocarbon gases depends upon the matching of burner and appliance design with certain gas characteristics. The most important of these are the Wobbe index [calorific value/(specific gravity)], and the flame speed, usually expressed as a factor or an arbitrary scale on which that of hydrogen is 100.

The Wobbe index – originally developed for natural gas but applicable to other gas streams – gives a measure of the heat input to an appliance through a given aperture at a given gas pressure. Using this as a vertical coordinate and the flame speed factor as the horizontal coordinate, a combustion diagram can be constructed for an appliance, or a whole range of appliances, with the aid of appropriate test gases. This diagram shows the area within which variations in the Wobbe index and of gases may occur for the given range of appliances without resulting in incomplete combustion or flame lift or the lighting back of pre-aerated flames. This method of prediction of combustion characteristics is not sufficiently accurate to eliminate entirely the need for the practical testing of new gases.

The carbon/hydrogen ratio is of importance since it is normally uneconomical to recover the latent heat of the water vapor resulting from combustion. This results in higher heat losses in waste gas from the combustion of gaseous hydrocarbon derivatives than from other fuels. This effect largely counteracts the higher combustion efficiency which would otherwise be obtainable from the use of hydrocarbon gases owing to their superior flexibility and controllability.

Analytical methods are available in standard form for determining volatile sulfur content and certain specific corrosive sulfur compounds that are likely to be present. Many laboratories use rapid combustion techniques with an oxy-hydrogen flame (ASTM D2784). Absorption methods are suitable for determination of particular sulfur compounds, while other procedures have been developed in which the sulfur compounds are titrated electrometrically after absorption in alkaline solutions.

Trace hydrocarbon derivatives that may be regarded as contaminants may be determined by the gas chromatographic methods already discussed. Heavier hydrocarbon derivatives in small amounts may not be completely removed from the column. If accurate information is required related to the nature and amount of high-boiling constituents, then temperature programming or a reconcentration procedure may be used.

The quantitative determination of water content is carried out by titration with Karl Fischer reagent, and analytical methods for determining traces of various other impurities are known to be in use. No published methods are available, but procedures based on standard analytical practice have been worked out for traces of ammonia, alkali, and alkali metals. The method for determination of inert gases in a gas stream based on absorption of the hydrocarbon derivatives in glacial acetic acid using an Orsat-type apparatus has been superseded by gas chromatography.

Once the composition of a mixture has been determined, it is possible to calculate various properties. Values which can be derived in this way include specific gravity, vapor pressure, calorific value, and dew point. Where it is necessary therefore to carry out the full analysis for some purpose, or where the facilities (gas chromatography) are available to do it, empirical tests may not be necessary.

One of the most widely used tests is vapor pressure (ASTM D126) which set out instructions for the test at 100°F (38°C). Simple evaporation tests in conjunction with vapor pressure measurement give a further guide to composition. In these tests, a gas stream is allowed to evaporate naturally from an open graduated vessel. Results are recorded on the basis of volume/temperature changes, such as the temperature recorded when 95% has evaporated, or volume left at a particular temperature. In one form of the test, the temperature is taken as the freezing point of mercury. The results are interpreted in relation to commercial butane or butane-propane mixtures.

Since dew point can be calculated from composition, direct determination of dew point for a particular gas stream type is a measure of composition. It is of more direct practical value, and if there are small quantities of higher molecular weight material present, it is preferable to use a direct measurement. The method is essentially a simple one of basic physics, but skill and experience are necessary to detect the haze formation correctly and to distinguish between the required hydrocarbon dew point and a film due to moisture. Equipment is available for both manual measurement and automatic recording of the dew point.

Specific gravity of the gas stream can be calculated, but if it is necessary to measure it, several pieces of apparatus are available; the determination can be carried out using a metal pressure pycnometer. Various procedures, manual, and recording, for specific gravity or density in the gaseous state are given in ASTM D1 070. Various types of calorimeter are available for the direct determination of calorific value. Suitable equipment is described in standard test methods ASTM D900 and ASTM D1826.

Corrosive sulfur compounds can be detected by their effect on copper and the form in which the general copper strip corrosion test and hydrogen sulfide can be detected by its action on moist lead acetate paper, and a procedure is also used as a measure of sulfur compounds.

Gas Cleaning

Gas cleaning (gas processing, gas refining) usually involves the use of several integrated unit processes to remove: (i) water, (ii) elements such as sulfur, helium, and carbon dioxide, and (iii) higher-boiling hydrocarbon derivatives, often referred to as gas liquids. In addition, it is often necessary to install scrubbers and heaters at or near the well-head that serve primarily to remove sand and other large-particle impurities. The heaters ensure that the temperature of the gas stream does not drop too low and form a hydrate with the water vapor content of the gas stream.

Gas cleaning, which involves a variety of methods (Table G-1), is a necessary step in many process industries in order to control the particulate matter emission and maintain a high level of environmental protection.

Table G-1 Summary of processes used for gas cleaning.

Separation concept	Process	Principle
Adsorption	Pressure Swing adsorption	Adsorption of CO ₂ using a molecular sieve
Physical absorption	Pressurized water wash	Dissolution of CO ₂
	Selexol, Rectisol, Purisol processes	Dissolution of CO ₂ in a specialized solvent
Chemical absorption	Alkanolamine wash	Chemical reaction of CO ₂ with the alkanolamine
Membrane separation	Polymer membrane (dry separation)	Membrane permeability of H ₂ S and CO ₂ is higher than CH ₄
Cryogenic process	Low temperature process	Phase transformation of CO ₂ to liquid; CH ₄ remains gaseous

Furthermore, in terms of their use as fuels or as feedstocks for the production fuels, gaseous products are experiencing a period of rapid development and, as a result, gas upgrading is attracting increasing attention. Currently, many of the gaseous products are used as on-site (refinery) fuel in power generators and boilers, and, for these uses, the hydrogen sulfide content in the gas should be less than 200 parts per million (ppm v/v) to ensure a long life for the power and heat generators. Consequently, the market for clean gas that is free of pollutants is facing significant challenges in terms of energy consumption and operating costs.

Many chemical processes are available for cleaning gas streams. However, there are many variables in the choice of process of the choice of refining sequence that dictate the choice of process or processes to be employed. In this choice, several factors must be considered: (i) the types and concentrations of contaminants in the gas, (ii) the degree of contaminant removal desired, (iii) the selectivity of acid gas removal required, (iv) the temperature, pressure, volume, and composition of the gas to be processed, (v) the carbon dioxide-hydrogen sulfide ratio in the gas, and (vi) the desirability of sulfur recovery due to process economics or environmental issues.

In addition to hydrogen sulfide and carbon dioxide, gas may contain other contaminants, such as mercaptans (also called *thiols*, R-SH) and carbonyl sulfide (COS). In fact, the variation in the composition of the gases that require cleaning either before being assigned to further use requires a variation of process types to ensure that specifications are met and the environment is protected. The presence of these impurities may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. However, these processes also capable of removing the acid gas impurities to very low levels when the acid gases are there in low-to-medium concentrations in the gas.

Process selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes remove both hydrogen sulfide and carbon dioxide; other processes are designed to remove hydrogen sulfide only. It is important to consider the process selectivity for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream.

The most common technologies utilized are venturi-type scrubbers, disintegrators, bag filters, and electrostatic precipitators. However, the selection of a cleaning technology (or technologies) is site-specific, case-sensitive, and dependent on the gas utilization requirements and local circumstances. However, it is important to recognize the composition of the gas so that the appropriate technologies can be selected for use to remove the specific contaminants. Thus, when any biomass-derived gas (either synthesis gas or bio-synthesis gas) is used for biofuel production, the cleaning of the raw gas is needed strictly in order to remove contaminants and potential catalyst poisons as well as to achieve the qualitative composition required before the gas is sold for use.

A gas stream gas, as produced by any methods such as anaerobic digestion, pyrolysis, or gasification, is typically saturated with water vapor and contains, in addition to methane (CH_4) and carbon dioxide (CO_2), various amounts of hydrogen sulfide (H_2S) as well as other contaminants that vary in amounts depending upon the composition of the feedstock and the process parameters employed for production of the gas. The properties of the contaminants are such that failure to remove them will make the gas unusable and even poisonous to the user. For example, hydrogen sulfide is a toxic gas, with a specific, unpleasant odor, similar to rotten eggs, forming acidic products in combination with the water vapor in the gas stream which can also result in corrosion of equipment. To prevent this, and a similar example of the adverse effects of other contaminants, the gas stream must be dried and any contaminants removed before the gas stream is sent to one or more conversion units or for sales.

Typically, in the gas cleaning industry (also called the *gas processing industry* or the *gas refining industry*), the feedstock is not used directly as fuel because of the complex nature of the feedstock and the presence of one or more of the aforementioned impurities that are corrosive or poisonous. It is, therefore, essential that any gas should be contaminant free when it enters any one of the various reactors. Typically, the primary raw gas stream has been subjected to chemical and/or physical changes (refining) after being produced. Thus, for many applications, the quality of the gas stream has to be improved. In addition, landfill gas often contains significant amounts of halogenated compounds which need to be removed prior to use. Occasionally, the oxygen content is high when air is allowed to invade the gas producer during collection of the landfill gas or when the biomass from which the gas is produced contains an abundance of oxygen-containing organic constituents.

The main contaminants (but not necessarily the only contaminants) that may require removal in gas cleaning systems are hydrogen sulfide, water, carbon dioxide, and halogenated compounds. Desulfurization prevents corrosion and avoids concentrations of the toxic hydrogen sulfide for safety in use and in the workplace. Also, if hydrogen sulfide and other sulfur-containing species such as thiol derivatives (RSH , also called mercaptan derivative) and carbonyl sulfide (COS) are not removed, combustion of the gas produces sulfur dioxide and sulfur trioxide which is even more poisonous than hydrogen sulfide. At the same time, the presence of sulfur dioxide in the gas stream lowers the dew point (the temperature to which the gas must be cooled to become saturated with water vapor) in the stack gas. The sulfurous acid formed (H_2SO_3) by reaction of the sulfur dioxide and the water vapor as well as the reaction of carbon dioxide and the water vapor form highly corrosive acidic species:

Thus, the removal of water from the gas stream is also essential, not only because of the potential for the reaction of water with contaminants in the gas stream but also because of potential accumulation of water vapor condensing in the gas line, the formation of a corrosive acidic solution when hydrogen sulfide is dissolved, or to achieve low dew points when the gas stream is stored under elevated pressures in order to avoid condensation and freezing. Also, if the non-combustible carbon dioxide is not removed, the energy content of the gas stream is diluted and there may also be an environmental impact due to the presence and emission of this contaminant.

Generally, the contaminants – not on any order of importance – are categorized as (i) condensable hydrocarbon derivatives, including tar products, (ii) alkali metals, such as sodium and potassium, (iii) nitrogen-containing derivatives, including ammonia and hydrogen cyanide, (iv) sulfur-containing derivatives, such as hydrogen sulfide, carbonyl sulfide, and carbon disulfide, (v) halogen-containing derivatives, such as hydrogen chloride and hydrogen bromide, and hydrogen fluoride, and (vi) particulate matter.

The constituents that make up the tar-like products that are formed during gasification when biomass decomposes in pyrolysis and gasification reactions are mostly oxygenated compounds that are decomposition products of biomass. These compounds react further and form secondary and tertiary tar compounds, which consist of compounds that do not exist in the source biomass. The secondary tar typically consists of alkylated one-ring and two-ring aromatic compounds (including heterocyclic compounds), whereas tertiary tar consists of aromatic hydrocarbon derivatives such as benzene, naphthalene, and various polycyclic aromatic hydrocarbon derivatives (PAHs, also called polynuclear aromatic compounds, PNAs). Tar constituents are typically classified on the basis of the number of rings (or the size of the condensed-ring systems) in the constituents or by boiling point distribution or physical properties. More generally, tar is defined as aromatic compounds that are higher-boiling than benzene and, in addition, an operational definition for tar depending on the end-use application has been used.

Process selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes remove both hydrogen sulfide and carbon dioxide; other processes are designed to remove hydrogen sulfide only. It is important to consider the process selectivity for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream.

Gas Cleaning – Alkali Washing Processes

Alkali washing processes typically fall under the general banner of *scrubber-based processes* (e.g., chemical scrubbers, gas scrubbers) which are a diverse group of gas cleaning processes that can be used to remove some particulate matter and/or gases from industrial exhaust streams (Figure 8.8). Traditionally, the term *scrubber* is used to refer to devices that use a liquid to wash and remove contaminants from gas streams. More recently, the term has also been used to describe systems that inject a dry reagent or a slurry into a contaminated gas stream to wash out acid gases.

The process efficiency for the removal of contaminants is improved by increasing the residence time of the gas stream in the scrubber or by increasing the surface area of the scrubber solution by the use of a spray nozzle or a packed tower. A wet scrubbing system has the potential to increase the proportion of water in the treated gas stream.

Wet scrubbers can also be used for heat recovery from hot gases by flue-gas condensation. In this option, water from the scrubber drain is circulated through a cooler to the nozzles at the top of the scrubber. The hot gas enters the scrubber at the bottom, and, if the gas temperature is above the dew point of the water, it is initially cooled by evaporation of the water drops. Further cooling causes water vapor to condense thereby adding to the amount of circulating water.

See also: Alkali Washing Process.

Gas Cleaning – Biological Methods

Biological processes have mainly been used to remove hydrogen sulfide. Hydrogen sulfide can be oxidized by microorganisms of the species *Thiobacillus* and *Sulfolobus*. The degradation requires oxygen, and therefore, a small amount of air (or pure oxygen if levels of nitrogen should be minimized) is added for biological desulfurization to take place. The degradation can occur inside the digester and can be facilitated by immobilizing the microorganisms occurring naturally in the digestate. An alternative is to use a trickling filter which the gas stream passes through when leaving the digester. In the trickling filter, the microorganisms grow on a packing material. A gas stream with added air meets a counterflow of water containing nutrients. The sulfur-containing solution is removed and replaced when the pH drops below a certain level. Both methods are widely applied; however, they are not suitable when the gas stream

is used as vehicle fuel or for grid injection due to the remaining traces of oxygen. An alternative system is available in which the absorption of the hydrogen sulfide is separated from the biological oxidation to sulfur – hence, the gas stream flow remains free of oxygen. There has also been focus on the removal of siloxane derivatives and carbon dioxide.

As another example, natural bacteria can convert hydrogen sulfide into elemental sulfur in the presence of oxygen and iron. This can be done by introducing a small amount (2 to 5%) of air into the head space of the digester. As a result, deposits of elemental sulfur will be formed in the digester. Even though this situation will reduce the hydrogen level, it will not lower it below that recommended for pipeline-quality gas. This process may be optimized by a more sophisticated design where air is bubbled through the digester feed material. It is critical that the introduction of the air be carefully controlled to avoid reducing the amount of the gas stream that is produced.

See also: Biofiltration, Bio-oxidation, Bioscrubbing.

Gas Cleaning – Chemisorption

Chemisorption (chemical absorption) processes are characterized by a high capability of absorbing large amounts of acid gases. They use a solution of a relatively weak base, such as monoethanolamine. The acid gas forms a weak bond with the base which can be regenerated easily. Monoethanolamine and diethanolamine derivatives are frequently used for this purpose. The amine concentration typically ranges between 15 and 30% w/w. The gas stream is passed through the amine solution where sulfides, carbonates, and bicarbonates are formed. Diethanolamine is a favored absorbent due to its lower corrosion rate, smaller amine loss potential, fewer utility requirements, and minimal reclaiming needs. Diethanolamine also reacts reversibly with 75% of carbonyl sulfides (COS), while the mono- reacts irreversibly with 95% of the carbonyl sulfide and forms a degradation product that must be disposed in an environmentally acceptable manner.

The ethanolamine process, known as the *Girbotol* process, removes acid gases (hydrogen sulfide and carbon dioxide) from gases. The Girbotol process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower (the absorber) through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator. Alkanolamine scrubbers can be used to remove hydrogen sulfide or hydrogen sulfide and carbon dioxide simultaneously. For instance, monoethanolamine (MEA), diethanolamine (DEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and triethanolamine (TEA) can be used. The alkanolamine scrubbing process is also carried out in two steps: the first step involves the amine contactor, and the second step involves the regenerator. In a process with diethanolamine and methyldiethanolamine, the main reactions in equilibrium in the system are:

The pH is an important parameter because it affects the concentration of the ionic species and therefore the reactions with the amines. Moreover, the temperature and pressure also have a significant effect on the process.

The reactions that involve carbon dioxide and hydrogen sulfide with amines are as follows:

This system is very complex due to the number of reactions involved, and other reactions may also occur in the system. Tertiary amines such as DMEA do not react directly with carbon dioxide, and hydrogen sulfide with amines is almost instantaneous by proton transfer. Thus, tertiary amines are used for selective hydrogen sulfide removal, and for selective hydrogen sulfide and carbon dioxide removal, a mixed amine system (tertiary and primary or secondary) is employed. Moreover, other compounds can be mixed with amine solutions.

Thus, treatment of a gas stream to remove the acid gas constituents (hydrogen sulfide and carbon dioxide) is most often accomplished by contact of the gas stream with an alkaline solution. The most commonly used treating solutions are aqueous solutions of the ethanolamine or alkali carbonates, although a considerable number of other treating agents have been developed in recent years. Most of these newer treating agents rely upon physical absorption and chemical reaction. When only carbon dioxide is to be removed in large quantities or when only partial removal is necessary, a hot carbonate solution or one of the physical solvents is the most economical selection.

The primary process for sweetening sour gas uses an amine (*olamine*) solution to remove the hydrogen sulfide (the *amine process*). The sour gas is run through a tower, which contains the olamine solution. There are two principle amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from the gas stream as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status. The amine solution used can be regenerated for reuse and, although most sour gas sweetening involves the amine absorption process, it is also possible to use solid desiccants like iron sponge to remove hydrogen sulfide and carbon dioxide, including bio-based iron sponge.

Diglycolamine (DGA) is another amine solvent used in the Econamine process in which absorption of acid gases occurs in an absorber containing an aqueous solution of diglycolamine, and the heated rich solution (saturated with acid gases) is pumped to the regenerator (Reddy and Gilmartin, 2008). Diglycolamine solutions are characterized by low freezing points, which make them suitable for use in cold climates.

The most well-known hydrogen sulfide removal process is based on the reaction of hydrogen sulfide with iron oxide (often also called the iron sponge process or the dry box method) in which the gas is passed through a bed of wood chips impregnated with iron oxide. The iron oxide is converted to the corresponding sulfur which is re-aerated by oxidation:

The iron oxide process (which was implemented during the 19th century and also referred to as the iron sponge process) is the oldest and still the most widely used batch process for sweetening the gas stream. The reaction can be exploited by adding the iron chloride to the digester feed material or passing the gas stream through a bed of

iron oxide-containing material. The iron oxide comes in different forms such as rusty steel wool, iron oxide pellets, or wood pellets coated with iron oxide. The iron oxide media needs to be replaced periodically. The regeneration process is highly exothermic and must be controlled to avoid problems.

In the process, the sour gas is passed down through the bed. In the case where continuous regeneration is to be utilized, a small concentration of air is added to the sour gas before it is processed. This air serves to continuously regenerate the iron oxide, which has reacted with hydrogen sulfide, which serves to extend the on-stream life of a given tower but probably serves to decrease the total amount of sulfur that a given weight of bed will remove. Ferric hydroxide $[\text{Fe}(\text{OH})_3]$ can also be used in this process.

The process is usually best applied to gases containing low-to-medium concentrations (300 ppm v/v) of hydrogen sulfide or mercaptan derivatives. This process tends to be highly selective and does not normally remove significant quantities of carbon dioxide. As a result, the hydrogen sulfide stream from the process is usually high purity. The use of iron oxide process for sweetening sour gas is based on adsorption of the acid gases on the surface of the solid sweetening agent followed by chemical reaction of ferric oxide (Fe_2O_3) with hydrogen sulfide:

The reaction requires the presence of slightly alkaline water, and a temperature below 43°C (110°F) and bed alkalinity (pH: 8 to 10) should be checked regularly, usually on a daily basis. The pH level is maintained through the injection of caustic soda with the water. If the gas does not contain sufficient water vapor, water may need to be injected into the incoming gas stream (i.e., the gas stream at the inlet).

The ferric sulfide produced by the reaction of hydrogen sulfide with ferric oxide can be oxidized with air to produce sulfur and regenerate the ferric oxide:

The regeneration step is exothermic, and air must be introduced slowly so the heat of reaction can be dissipated. If air is introduced quickly, the heat of reaction may ignite the bed. Some of the elemental sulfur produced in the regeneration step remains in the bed. After several cycles, this sulfur will form a cake over the ferric oxide, decreasing the reactivity of the bed. Typically, after 10 cycles, the bed must be removed and a new bed introduced into the vessel.

The iron oxide process is one of several metal oxide-based processes that scavenge hydrogen sulfide and organic sulfur compounds (mercaptan derivatives) from gas streams through reactions with the solid-based chemical adsorbent (Kohl and Riesenfeld, 1985). They are typically non-regenerable, although some are partially regenerable, losing activity upon each regeneration cycle. Most of the processes are governed by the reaction of a metal oxide with hydrogen sulfide to form the metal sulfide. For regeneration, the metal oxide is reacted with oxygen to produce elemental sulfur and the regenerated metal oxide. In addition, to iron oxide, the primary metal oxide used for dry sorption processes is zinc oxide.

In the zinc oxide process, the zinc oxide media particles are extruded cylinders 3-4 mm in diameter and 4 to 8 mm in length and react readily with the hydrogen sulfide:

At increased temperatures (205 to 370°C , 400 to 700°F), zinc oxide has a rapid reaction rate, therefore providing a short mass transfer zone, resulting in a short length of unused bed and improved efficiency.

Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the *Ferrox* process or the *Stretford* process. The *Ferrox* process is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The *Stretford* process employs a solution containing vanadium salts and anthraquinone disulfonic acid (Maddox, 1974; Mokhatab et al., 2006; Abdel-Aal et al., 2016).

Most hydrogen sulfide removal processes return the hydrogen sulfide unchanged, but if the quantity involved does not justify installation of a sulfur recovery plant (usually a Claus plant), it is necessary to select a process that directly produces elemental sulfur. In the *Beavon-Stretford* process, a hydrotreating reactor converts sulfur dioxide in the off-gas to hydrogen sulfide which is contacted with Stretford solution (a mixture of vanadium salt, anthraquinone disulfonic acid, sodium carbonate, and sodium hydroxide) in a liquid-gas absorber. The hydrogen sulfide reacts stepwise with sodium carbonate and anthraquinone disulfonic acid to produce elemental sulfur, with vanadium serving as a catalyst. The solution proceeds to a tank where oxygen is added to regenerate the reactants. One or more froth or slurry tanks are used to skim the product sulfur from the solution, which is recirculated to the absorber.

Even though the removal of hydrogen sulfide can be achieved by chemical or physical absorption, chemical scrubbers are the most commonly used systems for hydrogen sulfide removal. The most important processes are iron-based chelation methods and absorption by alkanolamines. In iron-based chelation processes, there are two main reactions:

The first step involves the chemical reaction to produce elemental sulfur, and in the second step, iron(III) is regenerated. Several commercial processes are based on iron chelation, such as the Lo-cat and Sulferox processes. Ethylenediaminetetraacetic acid (EDTA), hydroxyethylenediaminetriacetic acid (HEDTA), diethylenetriaminepentaacetic acid (DTPA), and nitrilotriacetic acid (NTA) are the most conventional ligands used in this process. The operating conditions are typically: 4 to 8°C (39.5 to 46.5°F), pH 4 to pH 8, iron concentration on the order of 1,000 to 10,000 ppm v/v with a chelant/iron ratio in the range 1.1 to 2.0.

The process using potassium phosphate is known as phosphate desulfurization, and it is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbon derivatives as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally. Processes using ethanolamine and potassium phosphate are now widely used.

Gas Cleaning – Effects of Gas Composition

Trace quantities of contaminants in hydrocarbon products can be harmful to many catalytic chemical processes in which these products are used. In general, the raw product gas of biomass gasification contains a range of minor species and contaminants, including particles, tar, alkali metals, chlorine compounds such as hydrogen chloride (HCl), nitrogen compounds such as ammonia (NH_3) and hydrogen cyanide (HCN), sulfur compounds such as hydrogen sulfide (H_2S) and carbonyl sulfide (COS), as well other species.

The maximum permissible levels of total contaminants are normally included in specifications for such hydrocarbon derivatives. It is recommended that this test method be used to provide a basis for agreement between two laboratories when the determination of sulfur in hydrocarbon gases is important. In the case of liquefied petroleum gas (LPG), total volatile sulfur is measured on an injected gas sample.

Acidic constituents such as carbon dioxide and hydrogen sulfide as well as thiol derivatives (RSH, also called mercaptan derivatives) can contribute to corrosion of refining equipment, harm catalysts, pollute the atmosphere, and prevent the use of hydrocarbon components in petrochemical manufacture. When the amount of hydrogen sulfide is high, it may be removed from a gas stream and converted to sulfur or sulfuric acid; a recent option for hydrogen sulfide removal is the use of chemical scavengers. Some gases contain sufficient carbon dioxide to warrant recovery as dry ice.

Many gas streams are not always truly hydrocarbon in nature and may contain contaminants, such as carbon oxides (CO_x , where $x = 1$ and/or 2), sulfur oxides (SO_x , where $x = 2$ and/or 3), as well as ammonia (NH_3), mercaptan derivatives (RSH), carbonyl sulfide (COS), and mercaptan derivatives (RSH). The presence of these impurities may eliminate some of the sweetening processes from use since some of these processes remove considerable amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes not designed to

remove (or incapable of removing) large amounts of acid gases, whereas they are capable of removing the acid gas impurities to low levels when the acid gases are present only in low-to-medium concentration in the gas.

The sources of the various gas streams are varied but, in terms of gas cleaning (i.e., removal of the contaminants before petrochemical production), the processes are largely the same but it is a question of degree. For example, gas streams from some sources may produce gases and may contain higher amounts of carbon dioxide and/or hydrogen sulfide, and the processes will have to be selected accordingly.

In addition to its primary importance as a fuel, a gas stream – such as synthesis gas – is also a source of hydrocarbon derivatives for petrochemical feedstocks. While the major hydrocarbon constituent of a gas stream is methane, there are components such as carbon dioxide (CO_2), hydrogen sulfide (H_2S), and mercaptan derivatives (thiols, also called mercaptans, RSH), as well as trace amounts of sundry other emissions such as carbonyl sulfide (COS). The fact that methane has a foreseen and valuable end-use makes it a desirable product, but in several other situations, it is considered a pollutant, having been identified a greenhouse gas.

In practice, heaters and scrubbers are usually installed at or near to the source. The scrubbers serve primarily to remove sand and other large-particle impurities, and the heaters ensure that the temperature of the gas does not drop too low. With gas that contains even low quantities of water, gas hydrates ($\text{C}_n\text{H}_{2n+2} \cdot x\text{H}_2\text{O}$) tend to form when temperatures drop. These hydrates are solid or semi-solid compounds, resembling ice-like crystals. If the hydrates accumulate, they can impede the passage of gas through valves and gathering systems (Zhang et al., 2007). To reduce the occurrence of hydrates, small gas-fired heating units are typically installed along the gathering pipe wherever it is likely that hydrates may form.

Gas Cleaning – Membrane Processes

Improvements in membrane technology have now made membranes competitive in other applications in the natural gas area. New membrane materials and configurations exhibit superior performance and offer improved stability against contaminants found in natural gas. The new membranes are targeted at three separations: nitrogen, carbon dioxide/hydrogen sulfide, and gas liquids. The process uses a two-step membrane system design; the methane-selective membranes do not need to be operated at low temperatures, and capital and operating costs are within economically acceptable limits.

The use of membranes has several advantages compared to the other technologies such as absorption and adsorption processes. For instance, the possibility of having a large membrane area in a small module volume due to high packing density allows lower space and weight requirements for membrane units for the same production, and consequently reduced investment. Moreover, the process is more environmentally friendly compared to the absorption process due to the non-use of chemicals. In addition to the previously mentioned advantages, membranes also have the advantage of reduced operating costs, no moving parts, and being suitable for remote locations. Its tolerance of motion makes membrane technology promising for offshore and subsea applications.

Several carbon dioxide selective membrane systems for carbon dioxide removal from natural gas have been installed onshore or topside on platforms, as listed in Table 1. For small fields with low carbon dioxide content in the gas stream, membrane systems work quite effectively, and the carbon dioxide content in the product can be quite close to the pipeline specification ($<2\%$). However, for bigger fields and high carbon dioxide content in the feed, the membrane-treated streams still have a high carbon dioxide content (e.g., $>6\%$) and need further treatment. For small fields, membrane technologies are economically competitive compared to absorption, while for large fields, absorption is still more favorable. However, due to limitations in weight and size on platforms, membrane processes can be more advantageous for offshore or subsea operations.

The membrane processes for carbon dioxide removal have been more extensively researched compared to hydrogen sulfide removal. Several commercial membrane processes for carbon dioxide removal are available. These membranes can tolerate variations in the carbon dioxide concentration in the feed stream within a large range (on the order of 3 to 90%). Also, membranes allow permeation of condensable vapors, such as C_{3+} hydrocarbon derivatives, aromatic derivatives, and water vapor, while rejecting the non-condensable gases, such as methane, ethane, nitrogen, and hydrogen. A membrane-based process for upgrading natural gas that contains C_{3+} hydrocarbon derivatives and/or acid gas is described. The conditioned natural gas can be used as fuel for gas-powered equipment, including compressors, in the gas field or the processing plant. Optionally, the process can be used to produce natural gas liquids.

Important factors for the selection of membrane material for carbon dioxide removal are high carbon dioxide permeability and carbon dioxide-methane selectivity, as well as high thermal and mechanical stability. The most commonly used commercial membranes for natural gas sweetening are cellulose acetate/triacetate and polyimide membrane. In recent years, a large number of membrane materials for carbon dioxide-methane separation have been developed and tested on a laboratory scale, including both inorganic and polymeric membrane materials.

The conventional polymeric membranes used in natural gas processing involve several challenges, typically including contamination, physical aging, and plasticization. The proper pretreatment of natural gas before membrane processes is important to avoid performance decline due to contamination; the different additives used in the oil and gas industry processing are destructive for membranes, and particles and viscous substances in the feed can block membrane pores. The main contaminants in carbon dioxide removal from natural gas are higher-molecular-weight hydrocarbon derivatives, BTEX (benzene, toluene, ethylene benzene, and xylenes), and hydrogen sulfide. The presence of higher-molecular-weight hydrocarbon derivatives in the membrane system decrease the membrane permeation ratio as the hydrocarbon derivatives slowly coat the membrane surface. The control of the humidity level of the gas is also important for some polymeric membranes, as water vapor causes swelling of the membranes and hence changes their performance.

Inorganic membranes have also been investigated for gas separation. Inorganic membranes can have higher selectivity and permeability compared to polymeric membranes. In general, inorganic membranes also have excellent resistance to harsh environments, and at high temperatures and pressures.

Gas Cleaning – Metal Oxide Processes

The use of solids for sweetening gas (typically in batch-type process) is based on adsorption of the acid gases on the surface of the solid sweetening agent, or reaction with some component on that surface. The solids processes are usually best applied to gases containing low-to-medium concentrations of hydrogen sulfide or mercaptan derivatives. The solids processes tend to be highly selective and do not normally remove significant quantities of carbon dioxide. Consequently, the regenerated hydrogen sulfide stream from the process is usually high purity and, in addition, pressure has relatively little effect on the adsorptive capacity of a sweetening agent.

Gas Cleaning – Methanol Based Processes

Methanol is probably one of the most versatile solvents in the natural gas processing industry. Historically, methanol was the first commercial organic physical solvent and has been used for hydrate inhibition, dehydration, gas sweetening, and liquids recovery. Most of these applications involve low temperature where methanol's physical properties are advantageous compared with other solvents that exhibit high viscosity problems or even solids formation. Operation at low temperatures tends to suppress methanol's most significant disadvantage, high solvent loss. Furthermore, methanol is relatively inexpensive and easy to produce making the solvent an attractive alternate for gas processing applications.

Methanol has favorable physical properties relative to other solvents except for vapor pressure. The benefits of the low viscosity of methanol at low temperature are manifested in the pressure drop improvement in the cold box of injection facilities and improved heat transfer. Methanol has a much lower surface tension relative to the other solvents. High surface tension tends to promote foaming problems in contactors. Methanol processes are probably not susceptible to foaming. However, the primary drawback of methanol is the high vapor pressure that is several times greater than that of the glycols or amines. To minimize methanol losses and enhance water and acid gas absorption, the absorber or separator temperatures are usually less than -20°F.

The high vapor pressure of methanol may initially appear to be a significant drawback because of high solvent losses. However, the high vapor pressure also has significant advantages. Although often not considered, lack of thorough mixing of the gas and solvent can pose significant problems. Because of the high vapor pressure, methanol is completely mixed in the gas stream before the cold box. Glycol derivatives, because they do not completely vaporize, may require special nozzles and nozzle placement in the cold box to prevent freeze-up. Solvent carry-over to other downstream processes may also represent a significant problem. Since methanol is more volatile than glycols,

amines, and other physical solvents including lean oil, methanol is usually rejected in the regeneration step of these downstream processes. The stripper concentrates the methanol in the overhead condenser where it can be removed and further purified. Unfortunately, if glycols are carried over to amine units, the glycol becomes concentrated in the solution and potentially starts to degrade and possibly dilute the amine solution.

The use of methanol has been further exploited in the development of the Rectisol process, either alone or as toluene-methanol mixtures are used to more selectively remove hydrogen sulfide and allow carbon dioxide to pass as the overhead product. Toluene has an additional advantage insofar as carbonyl sulfide (carbonyl sulfide) is more soluble in toluene than in methanol. The Rectisol process was primarily developed to remove both carbon dioxide and hydrogen sulfide (along with other sulfur-containing species) from gas streams resulting from the partial oxidation of coal, oil, and crude oil residua. The ability of methanol to absorb these unwanted components made it the natural solvent of choice. Unfortunately, at cold temperatures, methanol also has a high affinity for hydrocarbon constituents of the gas streams. For example, propane is more soluble in methanol than is carbon dioxide.

There are two versions of the Rectisol process – the two-stage and the once-through. The first step of the two-stage process is desulfurization before shift conversion; the concentrations of hydrogen sulfide and carbon dioxide are approximately 1 and 5% by volume, respectively. Regeneration of the methanol following the desulfurization of the feed gas produces high sulfur feed for sulfur recovery. The once-through process is only applicable for high pressure partial oxidation products. The once-through process is also applicable when the hydrogen sulfide to carbon dioxide content is unfavorable, in the neighborhood of 1:50.

The physical/chemical combined purification process in which the alkanolamine (mono- or di-ethanol amine) mixed with methanol are more successful than a single physical solvent used in many of the gas treatment plants. The main advantage of this solvent lies in the good physical absorption of physical solvent component in combination with the chemical reaction of the amine. The combination of a chemically active amine with a low boiling point polar physical solvent such as methanol offers major advantages in the absorption of carbon dioxide and sulfur components as: (i) low sulfur content in the product gas, (ii) low content of carbon dioxide in the purified gas, (iii) removal by absorption of trace components, such as hydrogen cyanide, carbonyl sulfide, mercaptan derivatives, and higher-molecular-weight hydrocarbon derivatives, (iv) relative low regeneration temperature since methanol has a boiling point lower than the boiling point of water, and (v) the solvent is non-corrosive so that carbon steel equipment can be used.

A process using methanol has been developed in which there is a simultaneous capability to dehydrate, to remove acid gas, and to control hydrocarbon dew point. The IFPEXOL-1 is used for water removal and hydrocarbon dew point control; the IFPEXOL-2 process is used for acid gas removal. The novel concept behind the IFPEXOL-1 process is to use a portion of the water-saturated inlet feed to recover the methanol from the aqueous portion of the low temperature separator. That approach has solved a major problem with methanol injection in large facilities, the methanol recovery via distillation. Beyond that very simple discovery, the cold section of the process is remarkably similar to a basic methanol injection process. Modifications to the process include water washing the hydrocarbon liquid from the low temperature separator to enhance the methanol recovery. The IFPEXOL-2 process for acid gas removal is very similar to an amine-type process except for the operating temperatures. The absorber operates below -20°F to minimize methanol losses, and the regenerator operates at approximately 90 psi. Cooling is required on the regenerator condenser to recover the methanol. This process usually follows the IFPEXOL-1 process, so excessive hydrocarbon absorption is not as great a problem.

Gas Cleaning – Molecular Sieve Processes

Molecular sieves can be used for removal of sulfur compounds from gas streams. Hydrogen sulfide can be selectively removed to meet 4 ppm v/v specification. The sieve bed can be designed to dehydrate and sweeten simultaneously. In addition, molecular sieve processes can be used for removal of carbon dioxide from gas streams.

Molecular sieves are a crystalline form of alkali metal (calcium or sodium) alumina-silicates, similar to natural clay minerals. They are highly porous, with a very narrow range of pore sizes, and high surface area. Manufactured by ion-exchange, molecular sieves are the most expensive adsorbents and possess highly localized polar charges on their surface that act as extremely effective adsorption sites for polar compounds such as water and hydrogen sulfide. Molecular sieves are alkaline and subject to attack by acids, but special acid-resistant sieves are available for very sour gases.

In a molecular sieve, the pore openings in a given structural are all the same size and are determined by the molecular structure of the crystal and the size of molecules present in the crystal. The pores are formed by driving off water of crystallization that is present during the synthesis process. Also, molecular sieves have the large surface area typical of any solid adsorbent; however, molecular sieves have highly localized polar charges. These localized charges are the reason for the strong adsorption of polar or polarizable compounds on molecular sieves. This also results in much higher adsorptive capacities for these materials by molecular sieves than by other adsorbents, particularly in the lower concentration ranges.

Since the pore size range is narrow, molecular sieves exhibit selectivity toward adsorbates on the basis of their molecular size and tend not to adsorb bigger molecules such as the higher-molecular-weight hydrocarbon derivatives. The regeneration temperature is high. They can produce a water content as low as 1 ppm. Molecular sieves offer a means of simultaneous dehydration and desulfurization and are therefore the best choice for sour gases.

Molecular sieves are highly selective for the removal of hydrogen sulfide (as well as other sulfur compounds) from gas streams and over continuously high absorption efficiency. They are also an effective means of water removal and thus offer a process for the simultaneous dehydration and desulfurization of gas. Gas that has excessively high water content may require upstream dehydration, however.

The molecular sieve process is similar to the iron oxide process. Regeneration of the bed is achieved by passing heated clean gas over the bed. As the temperature of the bed increases, it releases the adsorbed hydrogen sulfide into the regeneration gas stream. The sour effluent regeneration gas is sent to a flare stack, and up to 2% of the gas seated can be lost in the regeneration process. A portion of the natural gas may also be lost by the adsorption of hydrocarbon components by the sieve. In this process, unsaturated hydrocarbon components, such as olefins and aromatics, tend to be strongly adsorbed by the molecular sieves.

Molecular sieves are susceptible to poisoning by such chemicals as glycols and require thorough gas cleaning methods before the adsorption step. Alternatively, the sieve can be offered some degree of protection by the use of a guard bed in which a less expensive catalyst is placed in the gas stream before contact of the gas with the sieve, thereby protecting the catalyst from poisoning.

Regeneration of a molecular sieve bed concentrates the hydrogen sulfide into a small regeneration stream which must be treated or sent to disposal. During the regeneration cycle, the hydrogen sulfide will exhibit a peak concentration in the regeneration gas and the peak is approximately 30 times the concentration of the hydrogen sulfide in the inlet stream.

Gas Cleaning – Physical Solvent Processes

Two of the currently most-widely-used physical solvent processes for gas cleaning are Selexol process and the Rectisol process. The process solvent is a mixture of dimethyl ethers of polyethylene glycol [$\text{CH}_3(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_3$] where n is between 3 and 9. The solvent is chemically and thermally stable and has a low vapor pressure that limits its losses to the treated gas. The solvent has a high solubility for carbon dioxide, hydrogen sulfide, and carbonyl sulfide. It also has appreciable selectivity for hydrogen sulfide over carbon dioxide.

The principal benefits of physical solvents are: (i) high selectivity for hydrogen sulfide over carbonyl sulfide and carbon dioxide, (ii) high loadings at high acid gas partial pressures, (iii) solvent stability, and (iv) low heat requirements because most of the solvent can be regenerated by a simple pressure letdown. The performance of a physical solvent can be easily predicted. The solubility of a compound in the solvent is directly proportional to its partial pressure in the gas phase, hence, the improvement in the performance of physical solvent processes with increasing gas pressure. Physical solvent processes can be configured to take advantage of their high hydrogen sulfide/carbon dioxide selectivity together with high levels of carbon dioxide recovery.

In the Selexol process, the solvent is composed of a dimethyl ether of polyethylene glycol, which is chemically inert and not subject to degradation. The process also removes carbonyl sulfide, mercaptan derivatives, ammonia, hydrogen cyanide, and metal carbonyl derivatives. A variety of flow schemes permit process optimization and energy reduction, and the partial pressure of the acid gas is the key driving force. Typical feedstock conditions range between 300 and 2,000 psia, with acid composition (carbon dioxide plus hydrogen sulfide) from 5% v/v to more than 60% v/v by volume. The product specifications achievable depend on the application and can range from ppm up to percent levels of acid gas.

The Selexol process can be configured in various ways, depending on the requirements for the level of hydrogen sulfide/carbon dioxide selectivity, the depth of sulfur removal, the need for bulk carbon dioxide removal, and whether the gas needs to be dehydrated. The gas stream from the low-pressure flash is combined with the acid gas from the regenerator. This combined gas stream is then sent to a sulfur recovery unit. However, the hydrogen sulfide content could be too low for use in a conventional Claus process. The Selexol process can, however, be configured to give both a rich acid gas feed to the Claus unit as well as to provide for bulk carbon dioxide removal.

The Rectisol process is the most widely used physical solvent gas treating process for acid gas removal using an organic solvent at low temperatures. In general, methanol is used for removal of hydrogen sulfide, carbonyl sulfide, and carbon dioxide as well as removal of organic and inorganic impurities. It is possible to produce a clean gas with less than 0.1 ppm sulfur and a carbon dioxide content down to the ppm range. The main advantage over other processes is the use of a cheap, stable and easily available solvent, a very flexible process and low utilities.

The process is designed for the bulk removal of carbon dioxide and nearly all of the removal of hydrogen sulfide and carbonyl sulfide takes place in the bottom section of the absorber. The methanol solvent contacting the feed gas in the first stage of the absorber is stripped in two stages of flashing via pressure reduction. The regenerated solvent is virtually free of sulfur compounds but contains some carbon dioxide. The acid gas leaving the first stage solvent regenerator is suitable for a Claus plant. The second stage of absorption is designed for the removal of the remaining sulfur compounds and carbon dioxide. The solvent from the bottom of the second stage of the absorber is stripped deeply in a steam-heated regenerator and is returned to the top of the absorption column after cooling and refrigeration.

See also: Rectisol Process, Selexol Process, Sulfinol Process.

Gas Cleaning – Process Selection

Each of the gas cleaning processes has advantages relative to the others for certain applications; therefore, in selection of the appropriate process, the following facts should be considered: (i) tail gas clean-up requirements, (ii) type and concentration of impurities in the sour gas, (iii) specifications for the residue gas, (iv) specifications for the acid gas, (v) temperature and pressure at which the sour gas is available and at which the sweet gas must be delivered, (vi) volume of gas to be processed, (vii) hydrocarbon composition of the gas, and (viii) selectivity required for acid gas removal.

Furthermore, technologies in gas processing that have evolved considerably in the last four decades and have moved toward major trends in natural gas processing in the 21st century. These technologies have arisen to allow a much more rigorous optimization of several variables such as: (i) operational flexibility, and (ii) the types of gas that are offered from processing. Also, increased attention to thermodynamic efficiency and better use of refrigeration and recompression since 1980 have led to development of enhanced recovery processes for natural gas liquids.

Thus, the selection of an optimum process will depend on conditions and composition of the inlet gas, cost of fuel and energy, product specifications, and relative product values.

Decisions in selecting a gas treating process can many times be simplified by gas composition and operating conditions. High partial pressures (50 psi) of acid gases enhance the probability of using a physical solvent. The presence of significant quantities of higher-molecular-weight hydrocarbon derivatives in the feed discourages using physical solvents. Low partial pressures of acid gases and low outlet specifications generally require the use of amines for adequate treating.

In general, the batch and amine processes are used for over 90% of all onshore wellhead applications. Amine processes are preferred when the lower operating cost, the chemical cost for this process, is prohibitive, and justifies the higher equipment cost. The key is the sulfur content of the feed gas where below 20-pound sulfur per day, batch processes are more economical, and over 100-pound sulfur per day amine solutions are preferred.

One important aspect of gas processing that is not typically is the process for extraction (separation) of helium from gas stream. At present, there are a variety of techniques for separating and recovering helium from helium-bearing gas mixtures. Such techniques include (i) membrane technique, (ii) pressure swing adsorption technique, and (iii) cryogenic technique. Among these techniques, cryogenic processes are the most economical method and have been commonly used to produce helium at high recovery and/or purity from natural gas streams or other gas streams containing low purity helium. However, due to the standard boiling temperatures of methane, nitrogen, hydrogen, and helium, condensation-based distillation or an integrated process involving condensation, distillation, and cryogenics can be used to extract helium from natural gas streams. To meet the high requirements of the

product purities, the separation between methane and nitrogen by distillation process leaves the methane and other hydrocarbon derivatives the bottom product, while the overhead gas, which is the mixture of nitrogen, helium and hydrogen, can be further separated by cryogenic condensation process.

Gas Cleaning – Process Types

A gas stream gas can also be upgraded to pipeline-quality gas, and this upgraded gas may be used for residential heating and as vehicle fuel. When distributing the gas stream using pipelines, gas pipeline standards will, more than likely, become applicable. Removing water vapor is easier than removing carbon dioxide and hydrogen sulfide from the gas stream (Table G-2). A condensate trap at a proper location on the gas pipeline can remove water vapor as warm the gas stream cools by itself after leaving the digester or the gas-generating equipment.

Table G-2 Common methods for the removal of carbon dioxide and hydrogen sulfide from gas streams.

Carbon dioxide removal	Description
Water scrubbing	Uses principle of the higher solubility of carbon dioxide in water to separate the carbon dioxide from the gas. The process uses high pressure and removes hydrogen sulfide as well as carbon dioxide. The main disadvantage of this process is that it requires a large volume of water that must be purified and recycled.
Polyethylene glycol scrubbing	This process is more efficient than water scrubbing. It also requires the regeneration of a large volume of polyethylene glycol.
Chemical absorption	Chemical reaction between carbon dioxide and amine-based solvents (olamines).
Carbon molecular sieves	Uses differential adsorption characteristics to separate methane and carbon dioxide, which is carried out at high pressure (pressure swing adsorption). Hydrogen sulfide should be removed before the adsorption process.
Membrane separation	Selectively separates hydrogen sulfide from carbon dioxide from methane. The carbon dioxide and the hydrogen sulfide dissolve, while the methane is collected for use.
Cryogenic separation	Cooling until condensation or sublimation of the carbon dioxide.
Hydrogen sulfide removal	
Biological desulfurization	Natural bacteria can convert hydrogen sulfide into elemental sulfur in the presence of oxygen and iron. This can be done by introducing a small amount (2 to 5%) of air into the head space of the digester. As a result, deposits of elemental sulfur will be formed in the digester. This process may be optimized by a more sophisticated design where air is bubbled through the digester feed material. It is critical that the introduction of the air be carefully controlled to avoid reducing the amount of gas that is produced.
Iron/iron oxide reaction	Hydrogen sulfide reacts readily with either iron oxide or iron chloride to form insoluble iron sulfide. The reaction can be exploited by adding the iron chloride to the digester feed material or passing the gas through a bed of iron oxide-containing material. The iron oxide media needs to be replaced periodically. The regeneration process is highly exothermic and must be controlled to avoid problems.
Activated carbon	Activated carbon impregnated with potassium iodide can catalytically react with oxygen and hydrogen sulfide to form water and sulfur. The activated carbon beds need regeneration or replacement when saturated.
Scrubbing/membrane separation	The carbon dioxide and hydrogen sulfide can be removed by washing with water, glycol solutions, or separated using the membrane technique.

Gas processing involves the use of several different types of processes to remove contaminants from gas streams, but there is always overlap between the various processing concepts. In addition, the terminology used for gas processing can often be confusing and/or misleading because of the overlap. Gas processing is necessary to ensure that the gas prepared for transportation (usually by pipeline) and for sales must be as clean and pure as the specifications dictate. Thus, a gas stream, as it is used by consumers, is much different from the gas that is brought from, for example, the anaerobic digester. Moreover, although gas produced in the digester may be composed primarily of methane, it is by no means as pure.

The processes that have been developed to accomplish gas purification vary from a simple once-through wash operation to complex multi-step recycling systems. In many cases, the process complexities arise because of the need for recovery of the materials used to remove the contaminants or even recovery of the contaminants in the original, or altered, form. In addition to the corrosion of equipment by acid gases, the escape into the atmosphere of sulfur-containing gases can eventually lead to the formation of the constituents of acid rain, i.e., the oxides of sulfur (sulfur dioxide, SO_2 , and sulfur trioxide, SO_3). Similarly, the nitrogen-containing gases can also lead to nitrous and nitric acids (through the formation of the oxides NO_x , where $x = 1$ or 2) which are the other major contributors to acid rain. The release of carbon dioxide and hydrocarbon derivatives as constituents of refinery effluents can also influence the behavior and integrity of the ozone layer.

However, the precise area of application of a given process is difficult to predict and define and requires careful consideration of several process factors before process selection. These factors are: (i) the types of contaminants in the gas, (ii) the concentrations of contaminants in the gas, (iii) the degree of contaminant removal desired, (iv) the selectivity of acid gas removal required, (v) the temperature of the gas to be processed, (vi) the pressure of the gas to be processed, (vii) the volume of the gas to be processed, (viii) the composition of the gas to be processed, (ix) the ratio of carbon dioxide to hydrogen sulfide ratio in the gas feedstock, and (x) the desirability of sulfur recovery due to environmental issues or economic issues.

Finally, throughout the various cleaning processes, it is important to minimize the loss of methane in order to achieve an economical viable cleaning operation. However, it is also important to minimize the methane slip since methane is a strong greenhouse gas. Thus, the release of methane to the atmosphere should be minimized by treating the off-gas, air, or water streams leaving the plant even though the methane cannot be utilized. Methane can be present in the off-gas leaving a pressure swing adsorption-column, in air from a water scrubber with water recirculation or in water in a water scrubber without water recirculation.

Gas Cleaning – Removal of Acid Gases

In addition to water removal, one of the most important parts of gas processing involves the removal of hydrogen sulfide and carbon dioxide, which are generally referred to as contaminants. Gas streams from some sources contain significant amounts of hydrogen sulfide and carbon dioxide and, analogous to natural gas that contains these same impurities, is usually referred to as sour gas. Sour gas is undesirable because the sulfur compounds it contains can be extremely harmful, even lethal, to breathe and the gas can also be extremely corrosive. The process for removing hydrogen sulfide from sour gas is commonly referred to as *sweetening* the gas. Thus, sulfur compounds, mainly hydrogen sulfide, must be removed from the synthesis gas to the best possible extent since they can poison catalysts. The methanation catalyst is particularly prone to sulfur poisoning. Regenerative sorbents (so-called sulfur guards) can be used to reduce sulfur concentrations to the necessary limits, well below 1 ppm v/v. Washing techniques (based on physical or chemical adsorption) can also be implemented, making sulfur recovery via a Claus process possible if economically viable.

There are four general processes used for emission control (often referred to in another, more specific context as flue gas desulfurization: (i) physical adsorption in which a solid adsorbent is used, (ii) physical absorption in which a selective absorption solvent is used, (iii) chemical absorption in which a selective absorption solvent is used, (iv) and catalytic oxidation thermal oxidation.

Adsorption

Adsorption is a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. Activated carbon and molecular sieves are also capable of adsorbing water in addition to the acid gases.

In order to avoid any confusion, it must be emphasized here that *absorption* differs from *adsorption* in that absorption is not a physical-chemical surface phenomenon but a process in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). The process depends only on physical solubility and may include chemical reactions in the liquid phase (*chemisorption*). Common absorbing media used are water, aqueous amine solutions, caustic, sodium carbonate, and nonvolatile hydrocarbon oils, depending on the type of gas to be absorbed. In these processes, a solid with a high surface area is used. Molecular sieves (zeolites) are widely used and are capable of adsorbing large amounts of gas. In practice, more than one adsorption bed is used for continuous operation – one bed is in use, while the other is being regenerated.

On the other hand, adsorption is usually a gas-solid interaction in which an adsorbent such as activated carbon (the *adsorbent* or *adsorbing medium*) which can be regenerated upon *desorption*. The quantity of material adsorbed is proportional to the surface area of the solid, and, consequently, adsorbents are usually granular solids with a large surface area per unit mass. Activated carbon impregnated with potassium iodide can catalytically react with oxygen and hydrogen sulfide to form water and sulfur. The reaction is best achieved at 50 to 70°C (122 to 158°F) and 100 to 120 psi. The activated carbon adsorption beds must be regenerated or replaced before they become ineffective due to over-saturation.

Regeneration is accomplished by passing hot dry fuel gas through the bed. Molecular sieves are competitive only when the quantities of hydrogen sulfide and carbon disulfide are low. The captured (adsorbed) gas can be desorbed with hot air or steam, either for recovery or for thermal destruction. Adsorber units are widely used to increase a low gas concentration prior to incineration unless the gas concentration is high in the inlet air stream, and the process is also used to reduce problem odors (or obnoxious odors) from gases. There are several limitations to the use of adsorption systems, but it is generally the case that the major limitation is the requirement for minimization of particulate matter and/or condensation of liquids (e.g., water vapor) that could mask the adsorption surface and drastically reduce its efficiency.

Absorption

Absorption is achieved by dissolution (a physical phenomenon) or by reaction (a chemical phenomenon). In addition to economic issues or constraints, the solvents used for gas processing should have: (i) a high capacity for acid gas, (ii) a low tendency to dissolve hydrogen, (iii) a low tendency to dissolve low-molecular-weight hydrocarbon derivatives, (iv) low vapor pressure at operating temperatures to minimize solvent losses, (v) low viscosity, (vi) low thermal stability, (vii) absence of reactivity toward gas components, (viii) low tendency for fouling, (ix) a low tendency for corrosion, and (x) economically acceptable.

Noteworthy commercial processes used are the Selexol process, the Sulfinol process, and the Rectisol process. In these processes, no chemical reaction occurs between the acid gas and the solvent. The solvent, or absorbent, is a liquid that selectively absorbs the acid gases and leaves out the hydrocarbons.

The Selexol process uses a mixture of the dimethyl ether of propylene glycol as a solvent. It is nontoxic, and its boiling point is not high enough for amine formulation. The selectivity of the solvent for hydrogen sulfide (H_2S) is much higher than that for carbon dioxide (CO_2), so it can be used to selectively remove these different acid gases, minimizing carbon dioxide content in the hydrogen sulfide stream sent to the sulfur recovery unit (SRU) and enabling regeneration of solvent for carbon dioxide recovery by economical flashing. In the process, a gas stream is injected in the bottom of the absorption tower operated at 1,000 psi. The rich solvent is flashed in a flash drum (flash reactor) at 200 psi where methane is flashed and recycled back to the absorber and joins the sweet (low-sulfur or no-sulfur) gas stream. The solvent is then flashed at atmospheric pressure, and acid gases are flashed off. The solvent is then stripped by steam to completely regenerate the solvent, which is recycled back to the absorber. Any hydrocarbon derivatives are condensed, and any remaining acid gases are flashed from the condenser drum. This process is used when there is a high acid gas partial pressure and there are no high-boiling hydrocarbon derivatives. Diisopropanolamine (DIPA) can be added to this solvent to remove carbon dioxide to a level suitable for pipeline transportation.

The Sulfinol process uses a solvent that is a composite solvent, consisting of a mixture of diisopropanolamine (30 to 45% v/v) or methyl diethanolamine (MDEA), sulfolane (tetrahydrothiophene dioxide) (40 to 60% v/v), and water (5 to 15% v/v). The acid gas loading of the Sulfinol solvent is higher, and the energy required for its regeneration is lower than those of purely chemical solvents. At the same time, it has the advantage over purely physical solvents that

severe product specifications can be met more easily and co-absorption of hydrocarbon derivatives is relatively low. Aromatic compounds, higher-molecular-weight hydrocarbon derivatives, and carbon dioxide are soluble to a lesser extent. The process is typically used when the hydrogen sulfide-carbon dioxide ratio is greater than 1:1 or where carbon dioxide removal is not required to the same extent as hydrogen sulfide removal. The process uses a conventional solvent absorption and regeneration cycle in which the sour gas components are removed from the feed gas by countercurrent contact with a lean solvent stream under pressure. The absorbed impurities are then removed from the rich solvent by stripping with steam in a heated regenerator column. The hot lean solvent is then cooled for reuse in the absorber. Part of the cooling may be by heat exchange with the rich solvent for partial recovery of heat energy. The solvent reclaimer is used in a small ancillary facility for recovering solvent components from higher boiling products of alkanolamine degradation or from other high-boiling or solid impurities.

The big difference between water scrubbing and the Selexol process is that carbon dioxide and hydrogen sulfide are more soluble in Selexol which results in a lower solvent demand and reduced pumping. In addition, water and halogenated hydrocarbon derivatives (contaminants in gas streams from landfill sites) are removed when scrubbing the gas stream with Selexol in which the Selexol solvents is designed for recirculation. Due to formation of elemental sulfur stripping, the Selexol solvent with air is not recommended but with steam or inert gas (an upgraded gas stream). Removing hydrogen sulfide beforehand is an alternative.

Chemisorption

Chemisorption (chemical absorption) processes are characterized by a high capability of absorbing large amounts of acid gases. They use a solution of a relatively weak base, such as monoethanolamine. The acid gas forms a weak bond with the base which can be regenerated easily. Mono- and diethanolamine derivatives are frequently used for this purpose. The amine concentration normally ranges between 15 and 30%. The gas stream is passed through the amine solution where sulfides, carbonates, and bicarbonates are formed. Diethanolamine is a favored absorbent due to its lower corrosion rate, smaller amine loss potential, fewer utility requirements, and minimal reclaiming needs. Diethanolamine also reacts reversibly with 75% of carbonyl sulfides (COS), while the mono- reacts irreversibly with 95% of the carbonyl sulfide and forms a degradation product that must be disposed in an environmentally acceptable manner.

The ethanolamine process, known as the *Girbotol* process, removes acid gases (hydrogen sulfide and carbon dioxide) from gases. The Girbotol process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower (the absorber) through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

Alkanolamine scrubbers can be used to remove hydrogen sulfide or hydrogen sulfide and carbon dioxide simultaneously. For instance, monoethanolamine (MEA), diethanolamine (DEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and triethanolamine (TEA) can be used. The alkanolamine scrubbing process is also carried out in two steps: the first step involves the amine contactor, and the second step involves the regenerator. In a process with diethanolamine and methyldiethanolamine, the main reactions in equilibrium in the system are:

The pH is an important parameter because it affects the concentration of the ionic species and therefore the reactions with the amines. Moreover, the temperature and pressure also have a significant effect on the process.

The reactions that involve carbon dioxide and hydrogen sulfide with amines are as follows:

This system is complex due to the number of reactions involved, and other reactions may also occur in the system. Tertiary amines such as DMEA do not react directly with carbon dioxide, and hydrogen sulfide with amines is almost instantaneous by proton transfer. Thus, tertiary amines are used for selective hydrogen sulfide removal, and for selective hydrogen sulfide and carbon dioxide removal, a mixed amine system (tertiary and primary or secondary) is employed. Moreover, other compounds can be mixed with amine solutions.

Thus, treatment of a gas stream to remove the acid gas constituents (hydrogen sulfide and carbon dioxide) is most often accomplished by contact of the gas stream with an alkaline solution. The most commonly used treating solutions are aqueous solutions of the ethanolamine or alkali carbonates, although a considerable number of other treating agents have been developed in recent years. Most of these newer treating agents rely upon physical absorption and chemical reaction. When only carbon dioxide is to be removed in large quantities or when only partial removal is necessary, a hot carbonate solution or one of the physical solvents is the most economical selection.

The primary process for sweetening sour gas uses an amine (*olamine*) solution to remove the hydrogen sulfide (the *amine process*). The sour gas is run through a tower, which contains the olamine solution. There are two principle amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from the gas stream as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status. The amine solution used can be regenerated for reuse and, although most sour gas sweetening involves the amine absorption process, it is also possible to use solid desiccants like iron sponge to remove hydrogen sulfide and carbon dioxide, including bio-based iron sponge process.

Diglycolamine (DGA) is another amine solvent used in the Econamine process in which absorption of acid gases occurs in an absorber containing an aqueous solution of diglycolamine, and the heated rich solution (saturated with acid gases) is pumped to the regenerator. Diglycolamine solutions are characterized by low freezing points, which make them suitable for use in cold climates.

The most well-known hydrogen sulfide removal process is based on the reaction of hydrogen sulfide with iron oxide (often also called the iron sponge process or the dry box method) in which the gas is passed through a bed of wood chips impregnated with iron oxide. The iron oxide is converted to the corresponding sulfur which is reerated by oxidation:

The iron oxide process (which was implemented during the 19th century and also referred to as the iron sponge process) is the oldest and still the most widely used batch process for sweetening the gas stream. The reaction can be exploited by adding the iron chloride to the digester feed material or passing the gas stream through a bed of iron oxide-containing material. The iron oxide comes in different forms such as rusty steel wool, iron oxide pellets, or wood pellets coated with iron oxide. The iron oxide media needs to be replaced periodically. The regeneration process is highly exothermic and must be controlled to avoid problems.

In the process, the sour gas is passed down through the bed. In the case where continuous regeneration is to be utilized, a small concentration of air is added to the sour gas before it is processed. This air serves to continuously regenerate the iron oxide, which has reacted with hydrogen sulfide, which serves to extend the on-stream life of a given tower but probably serves to decrease the total amount of sulfur that a given weight of bed will remove. Ferric hydroxide $[\text{Fe}(\text{OH})_3]$ can also be used in this process.

The process is usually best applied to gases containing low-to-medium concentrations (300 ppm v/v) of hydrogen sulfide or mercaptan derivatives. This process tends to be highly selective and does not normally remove significant quantities of carbon dioxide. As a result, the hydrogen sulfide stream from the process is high purity. The use of iron oxide process for sweetening sour gas is based on adsorption of the acid gases on the surface of the solid sweetening agent followed by chemical reaction of ferric oxide (Fe_2O_3) with hydrogen sulfide:

The reaction requires the presence of slightly alkaline water and a temperature below 43°C (110°F), and bed alkalinity (pH: 8 to 10) should be checked regularly, usually on a daily basis. The pH level is maintained through the injection of caustic soda with the water. If the gas does not contain sufficient water vapor, water may need to be injected into the in-coming gas stream (i.e., the gas stream at the inlet).

The ferric sulfide produced by the reaction of hydrogen sulfide with ferric oxide can be oxidized with air to produce sulfur and regenerate the ferric oxide:

The regeneration step is exothermic, and air must be introduced slowly so the heat of reaction can be dissipated. If air is introduced quickly, the heat of reaction may ignite the bed. Some of the elemental sulfur produced in the regeneration step remains in the bed. After several cycles, this sulfur will form a cake over the ferric oxide, decreasing the reactivity of the bed. Typically, after 10 cycles, the bed must be removed and a new bed introduced into the vessel.

The iron oxide process is one of several metal oxide-based processes that scavenge hydrogen sulfide and organic sulfur compounds (mercaptan derivatives) from gas streams through reactions with the solid-based chemical adsorbent. They are typically non-regenerable, although some are partially regenerable, losing activity upon each regeneration cycle. Most of the processes are governed by the reaction of a metal oxide with hydrogen sulfide to form the metal sulfide. For regeneration, the metal oxide is reacted with oxygen to produce elemental sulfur and the regenerated metal oxide. In addition, to iron oxide, the primary metal oxide used for dry sorption processes is zinc oxide.

In the zinc oxide process, the zinc oxide media particles are extruded cylinders 3-4 mm in diameter and 4 to 8 mm in length and react readily with the hydrogen sulfide:

At increased temperatures (205 to 370°C, 400 to 700°F), zinc oxide has a rapid reaction rate, therefore providing a short mass transfer zone, resulting in a short length of unused bed and improved efficiency.

Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the *Ferrox* process or the Stretford process. The *Ferrox process* is based on the same chemistry as the iron oxide process except

that it is fluid and continuous. The *Stretford* process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

Most hydrogen sulfide removal processes return the hydrogen sulfide unchanged, but if the quantity involved does not justify installation of a sulfur recovery plant (usually a Claus plant), it is necessary to select a process that directly produces elemental sulfur. In the Beavon-Stretford process, a hydrotreating reactor converts sulfur dioxide in the off-gas to hydrogen sulfide which is contacted with Stretford solution (a mixture of vanadium salt, anthraquinone disulfonic acid, sodium carbonate, and sodium hydroxide) in a liquid-gas absorber. The hydrogen sulfide reacts stepwise with sodium carbonate and anthraquinone disulfonic acid to produce elemental sulfur, with vanadium serving as a catalyst. The solution proceeds to a tank where oxygen is added to regenerate the reactants. One or more froth or slurry tanks are used to skim the product sulfur from the solution, which is recirculated to the absorber.

Even though the removal of hydrogen sulfide can be achieved by chemical or physical absorption, chemical scrubbers are the most commonly used systems for hydrogen sulfide removal. The most important processes are iron-based chelation methods and absorption by alkanolamines. In iron-based chelation processes, there are two main reactions:

The first step involves the chemical reaction to produce elemental sulfur, and in the second step, iron(III) is regenerated. Several commercial processes are based on iron chelation, such as the Lo-cat and Sulferox processes. Ethylenediaminetetraacetic acid (EDTA), hydroxyethylenediaminetriacetic acid (HEDTA), diethylenetriaminepentaacetic acid (DTPA), and nitrilotriacetic acid (NTA) are the most conventional ligands used in this process. The operating conditions are typically: 4 to 8°C (39.5 to 46.5°F), pH 4 to pH 8, iron concentration on the order of 1,000 to 10,000 ppm v/v with a chelant/iron ratio in the range 1.1 to 2.0.

The process using potassium phosphate is known as phosphate desulfurization, and it is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbon derivatives as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally. Processes using ethanolamine and potassium phosphate are now widely used.

Other Processes

There is a series of alternate processes that involve (i) the use of chemical reactions to remove contaminants from gas streams or (ii) the use of specialized equipment to physically remove contaminants from gas streams.

As example of the first category, i.e., the use of chemical reactions to remove contaminants from gas streams, strong basic solutions are effective solvents for acid gases. However, these solutions are not normally used for treating large volumes of a gas stream because the acid gases form stable salts, which are not easily regenerated. For example, carbon dioxide and hydrogen sulfide react with aqueous sodium hydroxide to yield sodium carbonate and sodium sulfide, respectively.

However, a strong caustic solution is used to remove mercaptans from gas and liquid streams. In the Merox Process, for example, a caustic solvent containing a catalyst such as cobalt, which is capable of converting mercaptans (RSH) to caustic insoluble disulfides (RSSR), is used for streams rich in mercaptans after removal of hydrogen sulfide. Air is used to oxidize the mercaptan derivatives to disulfide derivatives. The caustic solution is then recycled for regeneration. The Merox process is mainly used for treatment of refinery gas streams.

As one of the major contaminants in gas streams, carbon dioxide must optimally be removed as it reduces the energy content of the gas and affect the selling price of the gas. Moreover, it becomes acidic and corrosive in the presence of water that has a potential to damage the pipeline and the equipment system. Hence, the presence of carbon dioxide in gas streams remains one of the challenging gas separation problems in process engineering for carbon dioxide/methane systems. Therefore, the removal of carbon dioxide from the gas stream through the purification processes is vital for an improvement in the quality of the product.

Carbonate washing is a mild alkali process (typically, the alkali is potassium carbonate, K_2CO_3 for gas processing for the removal of acid gases (such as carbon dioxide and hydrogen sulfide) from gas streams and uses the principle that the rate of absorption of carbon dioxide by potassium carbonate increases with temperature. It has been demonstrated that the process works best near the temperature of reversibility of the reactions:

The Fluor process uses propylene carbonate to remove carbon dioxide, hydrogen sulfide, carbonyl sulfide, water, and higher boiling hydrocarbon derivatives (C_2^+) from gas stream.

Water washing, in terms of the outcome, is almost analogous to (but often less effective than) washing with potassium carbonate, and it is also possible to carry out the desorption step by pressure reduction. The absorption is purely physical, and there is also a relatively high absorption of hydrocarbon derivatives, which are liberated at the same time as the acid gases. The water scrubbing process uses the higher solubility of carbon dioxide in water to separate the carbon dioxide from gas stream. This process is done under high pressure and removes hydrogen sulfide as well as carbon dioxide. The main disadvantage of this process is that it requires a large volume of water that must be purified and recycled. An analogous process, polyethylene glycol scrubbing, is similar to water scrubbing, but it is more efficient. However, the process does require the regeneration of a large volume of polyethylene glycol.

In chemical conversion processes, contaminants in gas emissions are converted to compounds that are not objectionable or that can be removed from the stream with greater ease than the original constituents. For example, a number of processes have been developed that remove hydrogen sulfide and sulfur dioxide from gas streams by absorption in an alkaline solution.

Catalytic oxidation is a chemical conversion process that is used predominantly for destruction of volatile organic compounds and carbon monoxide. These systems operate in a temperature regime on the order of 205 to 595°C (400 to 1,100°F) in the presence of a catalyst – in the absence of the catalyst, the system would require a higher operating temperature. The catalysts used are typically a combination of noble metals deposited on a ceramic base in a variety of configurations (e.g., honeycomb-shaped) to enhance good surface contact. Catalytic systems are usually classified on the basis of bed types such as *fixed bed* (or *packed bed*) and *fluid bed* (*fluidized bed*). These systems generally have high destruction efficiencies for most volatile organic compounds, resulting in the formation of carbon dioxide, water, and varying amounts of hydrogen chloride (from halogenated hydrocarbon derivatives). The presence in emissions of chemicals such as heavy metals, phosphorus, sulfur, chlorine, and most halogens in the incoming air stream act as poison to the system and can foul up the catalyst. Thermal oxidation systems, without the use of catalysts, also involve chemical conversion (more correctly, chemical destruction) and operate at temperatures in excess of 815°C (1,500°F), or 220 to 610°C (395 to 1,100°F) higher than catalytic systems.

Other processes include the *Alkazid process* for removal of hydrogen sulfide and carbon dioxide using concentrated aqueous solutions of amino acids. The hot potassium carbonate process decreases the acid content of natural and refinery gas from as much as 50% to as low as 0.5% and operates in a unit similar to that used for amine treating. The *Giammarco-Vetrocoke* process is used for hydrogen sulfide and/or carbon dioxide removal. In the hydrogen sulfide removal section, the reagent consists of sodium carbonate (Na_2CO_3) or potassium carbonate (K_2CO_3) or a mixture of the carbonates which contains a mixture of arsenite derivatives and arsenate derivatives; the carbon dioxide removal section utilizes hot aqueous alkali carbonate solution activated by arsenic trioxide (As_2O_3) or selenous acid (H_2SeO_3) or tellurous acid (H_2TeO_3). A word of caution might be added related to the last three chemicals which are toxic and can involve stringent environmental-related disposal protocols.

Molecular sieves are highly selective for the removal of hydrogen sulfide (as well as other sulfur compounds) from gas streams and offer continuously high absorption efficiency. They are also an effective means of water removal and thus offer a process for the simultaneous dehydration and desulfurization of gas. Gas that has excessively high water content may require upstream dehydration, however. The carbon molecular sieve method uses differential adsorption characteristics to separate methane and carbon dioxide.

In addition, the molecular sieve process is similar to the iron oxide process. Regeneration of the bed is achieved by passing heated clean gas over the bed. As the temperature of the bed increases, it releases the adsorbed hydrogen sulfide and the sour effluent regeneration gas is sent to a flare stack, and up to 2% v/v of the gas seated can be lost in the regeneration process. A portion of the gas stream may also be lost by the adsorption of hydrocarbon components by the sieve.

In this process, unsaturated hydrocarbon components, such as olefin derivatives and aromatic derivatives, tend to be strongly adsorbed by the molecular sieve. Molecular sieves are susceptible to poisoning by such chemicals as glycols and require thorough gas cleaning methods before the adsorption step. Alternatively, the sieve can be offered some degree of protection by the use of *guard beds* in which a less expensive catalyst is placed in the gas stream before contact of the gas with the sieve, thereby protecting the catalyst from poisoning. This concept is analogous to the use of guard beds or attrition catalysts in the crude oil industry.

Carbon molecular sieves are excellent products to separate specifically a number of different gaseous compounds in the gas stream. Thereby, the molecules are usually loosely adsorbed in the cavities of the carbon sieve but not irreversibly bound. The selectivity of adsorption is achieved by different mesh sizes and/or application of different gas pressures. When the pressure is released, the compounds extracted from the gas stream are desorbed. The process – pressure swing adsorption (PSA) technology – can be used to enrich methane from the gas stream in which the molecular sieve is applied which is produced from coke rich in pores in the micrometer range. The pores are then further reduced by cracking of the hydrocarbon derivatives.

In order to reduce the energy consumption for gas compression, a series of vessels are linked together. The gas pressure released from one vessel is subsequently used by the others. Usually four vessels in series are used filled with the molecular sieve which removes at the same time carbon dioxide and any water vapor. After removal of hydrogen sulfide, i.e., using activated carbon and water condensation in a cooler at 4°C, the gas stream flows at a pressure of 90 psi into the adsorption unit. The first column cleans the raw gas at 90 psi to an upgraded gas stream with a vapor pressure of less than 10 ppm water and a methane content of 96 % or more.

In the second column, the pressure of 90 psi is first released to approximately 45 psi by pressure communication with column 4, which was previously degassed by a slight vacuum. In a second step, the pressure is then reduced to atmospheric pressure. The released gas flows back to the digester in order to recover the methane. The third column is evacuated from 15 psi to 0.15 psi. The desorbed gas consists predominantly of carbon dioxide but also some methane and is therefore normally released to the environment. In order to reduce methane losses, the system can be designed with recirculation of the desorbed gases.

A number of other possible impurities, such as organic acids (e.g., formic and acetic acid) and unsaturated and higher boiling hydrocarbon derivatives, are normally not included in purity specifications for synthesis processes because they are already undesirable in upstream process stages of synthesis gas production (e.g., compression steps). However, organic compounds present must be below their dewpoint at pressure of the gas application to prevent condensation and fouling in the system. For organic compounds with sulfur or nitrogen heteroatoms (such as thiophene derivatives and pyridine derivatives), the additional specification applies that they need to be removed below ppm v/v level, as they are intrinsically poisonous for the catalyst.

Thiophene

Pyridine

Gas Cleaning – Removal of Alkali Metal Salts

Compared with fossil fuels, biomass is rich in alkali salts that typically vaporize at high gasifier temperatures but condense downstream below 600°C (1110°F). Methods are available to strip the alkali contents since condensation of alkali salts can cause serious corrosion problems. The alkali will condense onto fine solid particles and can be subsequently captured in a cyclone, electrostatic precipitators, or filters when the gas temperature is below 600°C (1,110°F). The hot gas can also be passed through a bed of active bauxite to remove alkali when cooling of gas is not permitted.

Gas Cleaning – Removal of Ammonia

Biomass with a relatively high nitrogen content will generate a product gas that contains ammonia (NH₃) and hydrogen cyanide (HCN) (Yuan et al., 2010) which, in turn, will generate nitrogen oxides (NO_x) during combustion. In the case of the gasification of biomass (to produce a gaseous product), the concentration of ammonia in the product gas depends not only on the nature of the biomass feedstock used but also on the gasifier design parameters and operating conditions.

Ammonia can be removed by wet scrubbing technology which has been widely adopted in the existing biomass gasification processes (Dou et al., 2002; Proell et al., 2005), and the ammonia can be removed when the gas is dried. As a result, a separate cleaning step is therefore usually not necessary.

Ammonia removal (often referred to as ammonia stripping) stripping is a desorption process used to lower the ammonia content of a wastewater stream. Some wastewaters contain large amounts of ammonia and/or nitrogen-containing compounds that may readily form ammonia. It is often easier and less expensive to remove nitrogen from wastewater in the form of ammonia than to convert it to nitrate-nitrogen before removal. Ammonia (a weak base) reacts with water (a weak acid) to form ammonium hydroxide. In ammonia stripping, lime or caustic is added to the wastewater until the pH reaches 10.8 to 11.5 standard units which converts ammonium hydroxide ions to ammonia gas according to the following reaction(s):

There are two process variations for ammonia stripping: the cross-flow tower, and (ii) the countercurrent tower. In a cross-flow tower, the solvent gas (air) enters along the entire depth of fill and flows through the packing, as the alkaline wastewater flows downward. In the countercurrent tower, air is drawn through openings at the bottom, as wastewater is pumped to the top of a packed tower. Free ammonia (NH₃) is stripped from falling water droplets into the air stream, then discharged to the atmosphere.

Compared with wet scrubbing technology, hot-gas cleanup technology, preferably employing catalysts, is more advantageous with respect to energy efficiencies as it eliminates the needs of cooling the product gas and re-heating again for the synthesis gas applications. Catalytic processes effectively remove ammonia by converting it to nitrogen, hydrogen, and water. Nickel-Ni-based catalysts have higher activity, while other catalysts do not have good potentials for ammonia.

Gas Cleaning – Removal of Condensable Hydrocarbons

Hydrocarbon derivatives that are higher molecular weight than methane that are present in the gas streams are valuable raw materials and important fuels. They can be recovered by lean oil extraction. The first step in this process is to cool the treated gas by exchange with liquid propane, after which the cooled gas is then washed with a cold hydrocarbon liquid, which dissolves most of the condensable hydrocarbon derivatives. The uncondensed gas is a dry gas stream and is composed mainly of methane. The dry gas stream may then be used either as a fuel or as a chemical

feedstock. Another way to recover any higher-molecular-weight hydrocarbon constituents from a gas stream is by using cryogenic cooling (cooling to low temperatures on the order of -100 to -115°C (-150 to -175°F), which are achieved primarily through lowering the temperatures to below the dew point.

To prevent hydrate formation, gas stream may be treated with glycols, which dissolve water efficiently. Ethylene glycol (EG), diethylene glycol (DEG), and triethylene glycol (TEG) are typical solvents for water removal. Triethylene glycol is preferable in vapor phase processes because of its low vapor pressure, which results in less glycol loss. The triethylene glycol absorber unit typically contains 6 to 12 bubble-cap trays to accomplish the water absorption. However, more contact stages may be required to reach dew points below -40°C (-40°F). Calculations to determine the number of trays or feet of packing, the required glycol concentration, or the glycol circulation rate require vapor-liquid equilibrium data. In addition, predicting the interaction between triethylene glycol and water vapor in the gas stream over a broad range allows the designs for ultra-low dew point applications to be made.

One alternative to using bubble-cap trays is the use of the adiabatic expansion of the inlet gas. In the process, the inlet gas is first treated to remove water and acid gases, then cooled via heat exchange and refrigeration. Further cooling of the gas is accomplished through turbo expanders, and the gas is sent to a demethanizer to separate methane from the higher-boiling hydrocarbon derivatives. Improved recovery of the higher-boiling hydrocarbon derivatives could be achieved through better control strategies and by use of on-line gas chromatographic analysis.

Membrane separation process are very versatile and are designed to process a wide range of feedstocks and offer a simple solution for removal and recovery of higher boiling hydrocarbon derivatives from gas streams. There are two membrane separation techniques: (i) high pressure gas separation and (ii) gas-liquid adsorption. The high pressure separation process selectively separates hydrogen sulfide and carbon dioxide from methane. Usually, this separation is performed in three stages and produces methane with a high degree of purity (on the order of 96% v/v methane).

The separation process is based on high-flux membranes that selectively permeates higher boiling hydrocarbon derivatives (compared to methane) and are recovered as a liquid after recompression and condensation. The residue stream from the membrane is partially depleted of higher boiling hydrocarbon derivatives, and is then sent to a sales gas stream. Gas permeation membranes are usually made with vitreous polymers that exhibit good selectivity, but, to be effective, the membrane must be very permeable with respect to the separation process.

Membrane separation is based on the selectivity properties of the membrane material. The driving force is the difference in chemical potential, which includes the effect of temperature and partial pressure regimes. Membranes can be operated at high pressure (>300 psi) or low pressure (120 to 150 psi). Several membranes can be used for gas stream upgrading, and these can be classified by the type of material: non-polymeric membranes (such as alumina, zeolites, and carbon), ceramic membranes, palladium membranes, and carbon molecular sieve membranes. Nevertheless, polymeric membranes are the most widely used because they are cheaper than inorganic membranes. Moreover, polymeric materials can be easily fabricated into flat sheets or asymmetric hollow fibers, both shapes that are usually used in industrial applications.

The material properties that define the performance are molecular structure, glass transition temperature, crystallinity, and degree of crosslinking. However, commercially available polymeric membranes are usually degraded by hydrogen sulfide, siloxanes, and/or volatile organic compounds. For instance, hydrogen sulfide can cause plasticization of glassy polymeric membranes, and this alters the polymeric structure and weakens the mechanical strength of the membrane.

In the high-pressure separation option, pressurized gas (36 bar) is first cleaned over, for example, an activated carbon bed to remove (halogenated) hydrocarbon derivatives and hydrogen sulfide from the raw gas as well as oil vapor from the compressors. The carbon bed is followed by a particle filter and a heater. The membranes made of acetate-cellulose separate small polar molecules such as carbon dioxide, moisture, and the remaining hydrogen sulfide.

The raw gas is upgraded in 3 stages to a clean gas with 96 % methane or more. The waste gas from the first two stages is recycled, and the methane can be recovered. The waste gas from stage 3 (and in part of stage 2) is flared or used in a steam boiler as it still contains 10 to 20 % v/v methane. First experiences have shown that the membranes can last up to 3 years which is comparable to the lifetime of membranes for gas purification – a primary market for membrane technology – which last typically two to five years.

The clean gas is further compressed up to 3,600 psi and stored in steel cylinders in high, medium, and low pressure banks. The membranes are specific for given molecules, i.e., hydrogen sulfide and carbon dioxide are upgraded

in different modules. The utilization of hollow-fiber membranes allows the construction of very compact modules working in cross flow.

The gas-liquid absorption membrane method is a separation technique which was developed for gas stream upgrading only recently. The essential element is a microporous hydrophobic membrane separating the gaseous from the liquid phase. The molecules from the gas stream, flowing in one direction, which are able to diffuse through the membrane will be absorbed on the other side by the liquid flowing in countercurrent.

The absorption membranes work at approx. atmospheric pressure (1 bar) which allows low-cost construction. The removal of gaseous components is very efficient. At a temperature of 25 to 35°C (77 to 95°F), the hydrogen sulfide concentration in the raw gas of 2% v/v is reduced to less than 0.025% v/v (250 ppm v/v) – the absorbent is sodium hydroxide (NaOH) or another alkaline material. Sodium hydroxide saturated with hydrogen sulfide can be used in water treatment to remove heavy metals. The concentrated hydrogen sulfide solution is fed into a Claus reaction or oxidized to elementary sulfur. The gas stream is upgraded very efficiently from 55% v/v methane (43% v/v carbon dioxide) to more than 96% methane. The amine solution is regenerated by heating, and the carbon dioxide released is pure and can be sold for industrial applications.

The main advantages of membranes are (i) safety and simplicity of operation, (ii) relative ease of maintenance and scale-up, (iii) excellent reliability, (iv) small footprint, and (v) operation without hazardous chemicals. Several operation modes can be employed – as an example, gas stream upgrading can be achieved by a two-stage cascade process with recycling and a single stage provided good flexibility for integration into upgraded gas streams.

Extraction

There are two principle techniques for removing higher-boiling hydrocarbon constituents from gas streams and are (i) the absorption method and (ii) the cryogenic expander process. In the latter process (the cryogenic expander process), a turboexpander is used to produce the necessary refrigeration and low temperatures, and high recovery of the low-boiling constituents, such as ethane and propane, can be attained. The gas stream is first dehydrated using a molecular sieve followed by cooling of the dry stream. The separated liquid containing most of the high-boiling fractions is then demethanized, and the cold gases are expanded through a turbine that produces the desired cooling for the process. The expander outlet is a two-phase stream that is fed to the top of the demethanizer column. This serves as a separator in which: (i) the liquid is used as the column reflux and the separator vapors combined with vapors stripped in the demethanizer are exchanged with the feed gas, and (ii) the heated gas, which is partially recompressed by the expander compressor, is further recompressed to the desired distribution pressure in a separate compressor.

The extraction of higher-boiling hydrocarbon constituents from the gas stream produces both a cleaner, purer gas stream, as well as the valuable hydrocarbon derivatives for use in, say, a petrochemical plant. This process allows for the recovery of approximately 90 to 95% v/v of the ethane originally in the gas stream. In addition, the expansion turbine is able to convert some of the energy released when the gas stream is expanded into recompressing the gaseous methane effluent, thus saving energy costs associated with extracting ethane.

Absorption

The absorption method of high-molecular-weight recovery of hydrocarbon derivatives is similar to using absorption for dehydration. The main difference is that, in the absorption of higher-boiling hydrocarbon constituents from the gas stream, absorbing oil is used as opposed to glycol. This absorbing oil has an affinity for the higher-boiling hydrocarbon constituents in much the same manner as glycol has an affinity for water. Before the oil has picked up any higher-boiling hydrocarbon constituents, it is termed *lean* absorption oil.

The *oil absorption process* involves the countercurrent contact of the lean (or stripped) oil with the incoming wet gas with the temperature and pressure conditions programmed to maximize the dissolution of the liquefiable components in the oil. The *rich* absorption oil (sometimes referred to as *fat* oil), containing higher-boiling hydrocarbon constituents, exits the absorption tower through the bottom. It is now a mixture of absorption oil, propane, butanes, pentanes, and other higher-boiling hydrocarbon derivatives. The rich oil is fed into lean oil stills, where the mixture is heated to a temperature above the boiling point of the higher-boiling hydrocarbon constituents but below that of the oil. This process allows for the recovery of higher-boiling constituents from the gas stream.

The basic absorption process is subject to modifications that improve process effectiveness and even to target the extraction of specific higher-boiling hydrocarbon constituents. In the refrigerated oil absorption method, where the lean oil is cooled through refrigeration, propane recovery can be on the order of 90%+ v/v and approximately 40% v/v of the ethane can be extracted from the gas stream. Extraction of the other, higher-boiling hydrocarbon constituents is typically near-quantitative using this process.

Fractionation

Fractionation processes are similar to those processes classed as *liquids removal* processes but often appear to be more specific in terms of the objectives: hence the need to place the fractionation processes into a separate category. The fractionation processes are those processes that are used (i) to remove the more significant product stream first, or (ii) to remove any unwanted low-boiling constituents from the higher-boiling liquid products.

In the general practice of gas processing, the first unit is a de-ethanizer followed by a depropanizer then by a debutanizer and, finally, a butane fractionator. Thus, each column can operate at a successively lower pressure, thereby allowing the different gas streams to flow from column to column by virtue of the pressure gradient, without necessarily the use of pumps. The purification of hydrocarbon gases by any of these processes is an important part of gas processing operations.

Thus, after any higher-boiling hydrocarbon constituents have been removed from the gas stream, they must be separated (fractionated) into the individual constituents prior to sales. The process of fractionation occurs in stages with each stage involving separation of the hydrocarbon derivatives as individual products. The process commences with the removal of the lower-boiling hydrocarbon derivatives from the feedstock. The particular fractionators are used in the following order: (i) the de-ethanizer, which is used to separate the ethane from the stream from the gas stream, (ii) the depropanizer, which is used to separate the propane from the de-ethanized gas stream, (iii) the debutanizer, which is used to separate the butane isomers, leaving the pentane isomers and higher-boiling hydrocarbon derivatives in the gas stream, and (iv) the butane splitter or de-isobutanizer, which is used to separate n-butane and iso-butane.

After the recovery of the higher-boiling hydrocarbon constituents, sulfur-free dry gas (methane) may be liquefied for transportation through cryogenic tankers. Further treatment may be required to reduce the water vapor below 10 ppm and carbon dioxide and hydrogen sulfide to less than 100 and 50 ppm v/v, respectively. Two methods are generally used to liquefy the gas: (i) the expander cycle and (ii) mechanical refrigeration. In the expander cycle, part of the gas is expanded from a high transmission pressure to a lower pressure. This lowers the temperature of the gas. Through heat exchange, the cold gas cools the incoming gas, which in a similar way cools more incoming gas until the liquefaction temperature of methane is reached.

In mechanical refrigeration, a multicomponent refrigerant consisting of nitrogen, methane, ethane, and propane is used through a cascade cycle. When these liquids evaporate, the heat required is obtained from the gas, which loses energy/temperature till it is liquefied. The refrigerant gases are recompressed and recycled.

Enrichment

The gas product must meet specific quality measures in order for the pipeline grid to operate properly. Consequently, gas stream which, in most cases contains contaminants, must be processed, i.e., cleaned, before it can be safely delivered to the high-pressure, long-distance pipelines that transport the product to the consuming public. A gas stream that is not within certain specific gravities, pressures, Btu content range, or water content levels will cause operational problems, pipeline deterioration, or can even cause pipeline rupture. Thus, the purpose of *enrichment* is to produce a gas stream for sale. Therefore, the process concept is essentially the separation of higher-boiling hydrocarbon constituents from the methane to produce a lean, dry gas.

As an example, carbon dioxide is to some extent soluble in water, and therefore, some carbon dioxide will be dissolved in the liquid phase of the digester tank. In upgrading with the in situ methane enrichment process, sludge from the digester is circulated to a desorption column and then back to the digester. In the desorption column, carbon dioxide is desorbed by pumping air through the sludge. The constant removal of carbon dioxide from the sludge leads to an increased concentration of methane in the gas stream phase leaving the digester.

The gas stream received and transported must (especially in the United States and many other countries) meet the quality standards specified by pipeline. These quality standards vary from pipeline to pipeline and are usually a

function of (i) the design of the pipeline system, (ii) the design of any downstream interconnecting pipelines, and (iii) the requirements of the customer. In general, these standards specify that the gas stream should (i) be within a specific Btu content range, typically $1,035 \text{ Btu ft}^3 \pm 50 \text{ Btu ft}^3$, (ii) be delivered at a specified hydrocarbon dew point temperature level to prevent any vaporized gas liquid in the mix from condensing at pipeline pressure, (iii) contain no more than trace amounts of elements such as hydrogen sulfide, carbon dioxide, nitrogen, water vapor, and oxygen, and (iv) be free of particulate solids and liquid water that could be detrimental to the pipeline or its ancillary operating equipment. Gas processing equipment, whether in the field or at processing/treatment plants, assures that these specifications can be met.

In most cases, processing facilities extract contaminants and higher-boiling hydrocarbon derivatives from the gas stream but, in some cases, the gas processors blend some higher-boiling hydrocarbon derivatives into the gas stream in order to bring it within acceptable Btu levels. For instance, in some areas, if the produced gas (including coalbed methane) does not meet (or is below) the Btu requirements of the pipeline operator, in which case a blend of higher Btu-content gas stream or a propane-air mixture is injected to enrich the heat content (Btu value) prior for delivery to the pipeline.

The number of steps and the type of techniques used in the process of creating a pipeline-quality gas stream most often depends upon the source and makeup of the wellhead production stream. Among the several stages of gas processing are: (i) gas-oil separation, (ii) water removal, (iii) liquids removal, (iv) nitrogen removal, (v) acid gas removal, and (vi) fractionation.

In many instances, pressure relief at the wellhead will cause a natural separation of gas from oil (using a conventional closed tank, where gravity separates the gas hydrocarbon derivatives from the heavier oil). In some cases, however, a multi-stage gas-oil separation process is needed to separate the gas stream from the crude oil. These gas-oil separators are commonly closed cylindrical shells, horizontally mounted with inlets at one end, an outlet at the top for removal of gas, and an outlet at the bottom for removal of oil. Separation is accomplished by alternately heating and cooling (by compression) the flow stream through multiple steps. However, the number of steps and the type of techniques used in the process of creating a pipeline-quality gas stream most often depends upon the source and makeup of the gas stream. In some cases, several of the steps may be integrated into one unit or operation, performed in a different order or at alternative locations (lease/plant), or not required at all.

Gas Cleaning – Removal of Nitrogen

Nitrogen may often occur in sufficient quantities in gas streams and, consequently, lowers the heating value of the gas, and the nitrogen must be removed. However, it must be recognized that nitrogen removal requires liquefaction and fractionation of the entire gas stream, which may affect process economics. In some cases, the nitrogen-containing gas stream is blended with a gas having a higher heating value and sold at a reduced price depending upon the thermal value (Btu/ft^3).

For high flow-rate gas streams, a cryogenic process is typical and involves the use of the different volatility of methane (b.p. $-161.6^\circ\text{C}/-258.9^\circ\text{F}$) and nitrogen (b.p. $-195.7^\circ\text{C}/-320.3^\circ\text{F}$) to achieve separation. In the process, a system of compression and distillation columns drastically reduces the temperature of the gas mixture to a point where methane is liquefied and the nitrogen is not. On the other hand, for smaller volumes of gas, a system utilizing pressure swing adsorption is a more typical method of separation.

The pressure swing adsorption process is a fixed-bed adsorption process that is carried out at constant temperature and variable pressure. In the process, carbon dioxide is separated from the gas stream by adsorption on a surface under elevated pressure. The adsorbing material, usually activated carbon or zeolites, is regenerated by a sequential decrease in pressure before the column is reloaded again. An upgrading plant, using this technique, typically has four, six, or nine vessels working in parallel. When the adsorbing material in one vessel becomes saturated, the raw gas flow is switched to another vessel in which the adsorbing material has been regenerated. During regeneration, the pressure is decreased in several steps. The gas that is desorbed during the first and eventually the second pressure drop may be returned to the inlet of the raw gas, since it will contain some methane that was adsorbed together with carbon dioxide. The gas desorbed in the following pressure reduction step is either led to the next column, or if it is almost entirely methane-free, it is released to the atmosphere. If hydrogen sulfide is present in the raw gas, it will be

irreversibly adsorbed on the adsorbing material. In addition, water present in the raw gas can destroy the structure of the material. Therefore, hydrogen sulfide and water need to be removed before the pressure swing adsorption column.

Thus, the pressure swing adsorption process enables the separation of carbon dioxide from a gas stream. Nevertheless, pressure swing adsorption can be used for the separation of other compounds such as nitrogen, oxygen, and carbon monoxide. Several packing materials can be used for the removal of carbon dioxide, and these include zeolite, silica gel, and activate carbon. In order to be effective continuously, the pressure swing adsorption process is composed of various fixed-bed columns running in alternative cycles of adsorption, regeneration, and pressure build-up. In some cases, the regeneration step is carried out under vacuum, and this technology is known as vacuum swing adsorption (VSA), which requires a vacuum pump at the outlet.

Moreover, the regeneration step can be carried out by increasing the temperature to enhance the desorption of compounds such as hydrogen sulfide (which is strongly adsorbed on the packing material). On increasing the temperature at constant pressure, the process is also known as temperature swing adsorption (TSA). The temperature swing adsorption process is used for gas sweetening. The gas stream must be fed dry into pressure swing adsorption, vacuum swing adsorption, and temperature swing adsorption processes, and the water content must therefore be reduced prior to these treatments.

The pressure swing adsorption operation can be based on equilibrium or kinetic separation. The more strongly adsorbed and faster diffusing compounds are retained on the packing material in equilibrium and kinetic separation, respectively. Natural zeolites have been used for hydrogen sulfide and carbon dioxide removal by pressure swing adsorption with thermal desorption working at 25°C (77°F) in the pressure range 45 to 100 psi. However, variations in the concentration of carbon dioxide can affect the performance of the pressure swing adsorption process. For example, an increase of 5% in the flow rate of the carbon dioxide can lead to an increase in the temperature at the top of the packed bed – thus, the use of a thermocouple could enhance the control strategy.

Also, in pressure swing adsorption method, methane and nitrogen can be separated by using an adsorbent with an aperture size close to the molecular diameter of the larger species (the methane) which allows nitrogen to diffuse through the adsorbent. This results in a purified gas stream that is suitable for pipeline specifications. The adsorbent can then be regenerated, leaving a highly pure nitrogen stream. The pressure swing adsorption method is a flexible method for nitrogen rejection, being applied to both small and large flow rates.

Gas Cleaning – Removal of Particulate Matter

Particulate matter that is present in the product gas can also be a serious problem for some end-users, and catalysts used for cleaning product gases have been demonstrated to be negatively affected by particulate matter.

Particulate matter can be removed using standard technologies such as cyclones, filters, and separators, which also reduce the tar content of the gas stream, the extent of tar removal depending on the particle separation technology used. The presence of alkali is of particular importance because alkali can form silicates with low melting temperatures that may negatively affect the filter operation.

Gas Cleaning – Removal of Siloxane Derivatives

Siloxane compounds are a subgroup of silicone derivatives containing silicon-oxygen (Si-O) bonds with organic radicals which are widely used for a variety of industrial processes. Siloxanes are used in products such as deodorants and shampoos, and can therefore be found in gas streams from sewage sludge treatment plants and in landfill gas. When siloxanes are burned, silicon oxide, a white powder, is formed which can create a problem in gas engines. Although most siloxanes disperse into the atmosphere where they are decomposed, some end up in wastewater, but more generally, siloxane derivatives generally end up as a significant component in the sludge.

As sludge undergoes anaerobic digestion, it may be subjected to temperatures up to 60°C (140°F). At this point, the siloxanes contained in the sludge will volatilize and become an unwanted constituent of the resulting gas stream.

This problem can be exacerbated by the fact that silicone-based anti-foaming agents are frequently added to the anaerobic digesters and these silicones sometimes biodegrade into siloxanes. Unfortunately, when siloxanes gasses are burned, they are usually converted into silicon dioxide particles, which are chemically and physically similar to sand.

Currently, there are six primary technologies for removing siloxanes from gas streams and include the following process options: (i) activated carbon is widely used to remove organic substances from gases and liquids due to its superior adsorbent properties, (ii) activated alumina (Al_2O_3) absorbs siloxanes from the gas stream; when the alumina becomes saturated, the absorption capability can be recovered by passing a regeneration gas through it, (iii) refrigeration with condensation in combination can be used to selectively remove specific compounds by lowering the temperature or pressure of the gas, and then allowing the compound to precipitate out to a liquid, and then settle out, (iv) synthetic resins remove volatile materials through adsorption. They can be specially formulated to remove specific classes of compounds, (v) liquid absorbents are used by a small number of landfill operators to treat the gas stream prior to use in combustion devices such as gas turbines, and (vi) membrane technology is a relatively recent development for siloxane removal; however, membranes are subject to acid deterioration from the acidic content usually found in raw gas stream. Of these technologies, activated carbon appears to be among the most dominant in the industry.

Gas Cleaning – Removal of Tar

Tar is a highly viscous liquid product (typically produced in thermal processes) that condenses in the low temperature zones of the equipment (the pyrolyzer or the gasifier), thereby interfering with the gas flow and leading to system disruption. It is, perhaps, the most undesirable product of the process and high residual tar concentrations in the can gas prevent utilization (Devi et al., 2003; Torres et al., 2007; Anis and Zainal, 2011; Huang et al., 2011). Methods for reduction or elimination of tar can be divided into two broad groups: (i) in situ tar reduction, also called primary tar reduction, which focuses on reducing or avoiding tar formation in the reactor, and (ii) post gasification tar reduction, also called or secondary tar reduction, which strips the tar from the product gas. A combination of in situ and post-gasification tar reductions can prove to be more effective than either of the single stages alone. The two basic post-gasification methods are physical removal and cracking (catalytic or thermal).

Physical Methods

In a process for the physical removal of tar, the tar is treated tar as dust particles or mist and the tar is condensed before separation. Physical tar removal can be accomplished by cyclones, barrier filters, wet electrostatic precipitators (ESPs), or wet scrubbers. The selection of the equipment application depends on the load concentrations of particulate matter (PM) and tar, particle size distribution, and particulate tolerance of downstream users.

Cyclone collectors are the most common of the inertial collector class and are effective in removing coarser fractions of particulate matter and operate by contacting the particles in the gas stream with a liquid. In principle the particles are incorporated in a liquid bath or in liquid particles which are much larger and therefore more easily collected. In the process, the particle-laden gas stream enters an upper cylindrical section tangentially and proceeds downward through a conical section. Particles migrate by centrifugal force generated by providing a path for the carrier gas to be subjected to a vortex-like spin. The particles are forced to the wall and are removed through a seal at the apex of the inverted cone. A reverse-direction vortex moves upward through the cyclone and discharges through a top center opening. Cyclones are often used as primary collectors because of their relatively low efficiency (50 to 90% is usual).

Cyclones may not be efficient when removing small tar droplets, and barrier filters are porous material which can capture a certain amount of tar when the product gas passes through the filters. As an aid, catalyst grains can be integrated as a fixed bed inside the filter to promote the simultaneous removal of particulate matter and tar.

Fabric filters are typically designed with non-disposable filter bags. As the gaseous (dust-containing) emissions flow through the filter media (typically cotton, polypropylene, fiberglass, or Teflon), particulate matter is collected on the bag surface as a dust cake. Fabric filters operate with collection efficiencies up to 99.9%, although other advantages are evident, but there are several issues that arise during use of such equipment.

Wet scrubbers are devices in which a countercurrent spray liquid is used to remove particles from an air stream. Device configurations include plate scrubbers, packed bed scrubbers, orifice scrubbers, venturi scrubbers, and spray towers, individually or in various combinations. Wet scrubbers can achieve high collection efficiencies at the expense of prohibitive pressure drops. The *foam scrubber* is a modification of a wet scrubber in which the particle-laden gas is passed through a foam generator, where the gas and particles are enclosed by small bubbles of foam.

Other methods include use of high-energy input venturi scrubbers or electrostatic scrubbers where particles or water droplets are charged, and flux force/condensation scrubbers where a hot humid gas is contacted with cooled liquid or where steam is injected into saturated gas. In the latter scrubber, the movement of water vapor toward the cold water surface carries the particles with it (diffusiophoresis), while the condensation of water vapor on the particles causes the particle size to increase, thus facilitating collection of fine particles.

Electrostatic precipitators operate on the principle of imparting an electric charge to particles in the incoming air stream, which are then collected on an oppositely charged plate across a high-voltage field. Particles of high resistivity create the most difficulty in collection. Conditioning agents such as sulfur trioxide (SO_3) have been used to lower resistivity. Important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles). Techniques under study include the use of high-voltage pulse energy to enhance particle charging, electron-beam ionization, and wide plate spacing. Electrical precipitators are capable of efficiencies >99% under optimum conditions, but performance is still difficult to predict in new situations.

Wet electrostatic precipitator units have a high collection efficiency (on the order of 90%) over the entire range of particle size down to 0.5 μm with a very low-pressure drop. Wet scrubbers can achieve a high collection efficiency (also on the order of 90%) as well.

Thermal Methods

Cracking methods are more advantageous in terms of recovering the energy content in the tar by converting the high-molecular-weight constituents of the tar into lower-molecular-weight (gaseous) products such as hydrocarbon derivatives and hydrogen at high temperature (up to 1,200°C, 2,190°F) or catalytic reactions (up to 800°C, 1,470°F). Catalytic cracking is commercially used in many refinery plants and has been demonstrated to be one of the most effective processes for the conversion of high-molecular-weight products (such as crude oil residua, heavy crude oil, extra heavy oil, and tar sand bitumen) into gases and lower-molecular-weight distillable and liquids.

Non-metallic catalysts such as dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$), calcite (CaCO_3), and zeolite and metallic catalysts such as nickel-based catalysts, nickel/molybdenum-based catalysts, nickel/cobalt-based catalysts, molybdenum-based catalysts, platinum-based catalysts, and ruthenium-based catalysts Mo, NiO, Pt and Ru have been applied to various tar conversion processes.

Tar removal can also be achieved by catalytic reforming which has the advantage of keeping the carbon contained in the tars available for further conversion to fuel. Another option to reduce the tar content of the synthesis gas is the use of catalytic bed material in the gasification reactor. Olivine sand has been shown to effectively reduce the tar content in a gas stream from steam gasification.

Gas Cleaning – Sulfur Recovery Processes

Sulfur is present in many gas streams principally as hydrogen sulfide as well as sulfur-containing compounds which are converted to hydrogen sulfide during processing. The hydrogen sulfide, together with some or all of any carbon dioxide present, is removed from the natural gas or refinery gas by means of one gas treating process.

The side stream from acid gas treating units consists mainly of hydrogen sulfide or carbon dioxide. Carbon dioxide is usually vented to the atmosphere but sometimes is recovered for carbon dioxide floods. Hydrogen sulfide could be routed to an incinerator or flare, which would convert the hydrogen sulfide to sulfur dioxide. The release of hydrogen sulfide to the atmosphere may be limited by environmental regulations. There are many specific restrictions on these limits, and the allowable limits are revised periodically. In any case, environmental regulations severely restrict the amount of hydrogen sulfide that can be vented or flared in the regeneration cycle.

Most sulfur recovery processes use chemical reactions to oxidize hydrogen sulfide and produce elemental sulfur. These processes are generally based either on the reaction of hydrogen sulfide and oxygen or hydrogen sulfide and sulfur dioxide. Both reactions yield water and elemental sulfur. These processes are licensed and involve specialized catalysts and/or solvents. These processes can be used directly on the produced gas stream. Where large flow rates are encountered, it is more common to contact the produced gas stream with a chemical or physical solvent and use a direct conversion process on the acid gas liberated in the regeneration step.

Gas Cleaning – Water Removal

The relative humidity of the gas stream inside the digester is 100%, so the gas is saturated with water vapors. To protect the energy conversion equipment from wear and from eventual damage, water must be removed from the produced gas stream. The quantity of water contained by the gas stream depends on temperature. A part of the water vapor can be condensed by cooling of the gas. This is frequently done in the gas pipelines transporting the gas stream from digester to a unit in which the water condensates on the walls of the sloping pipes and can be collected in a condensation separator, at the lowest point of the pipeline.

Water in the liquid phase causes corrosion or erosion problems in pipelines and equipment, particularly when carbon dioxide and hydrogen sulfide are present in the gas. The simplest method of water removal (refrigeration or cryogenic separation) is to cool the gas to a temperature at least equal to or (preferentially) below the dew point.

In addition to separating any condensate from the wet gas stream, it is necessary to remove most of the associated water. Most of the liquid, free water associated with the extracted gas stream, is removed by simple separation methods; however, the removal of the water vapor that exists in solution in a gas stream requires a more complex treatment. This treatment consists of dehydrating the gas stream, which usually involves one of two processes: either absorption or adsorption.

Moisture may be removed from hydrocarbon gases at the same time as hydrogen sulfide is removed. Moisture removal is necessary to prevent harm to anhydrous catalysts and to prevent the formation of hydrocarbon hydrates (e.g., $C_3H_8 \cdot 18H_2O$) at low temperatures. A widely used dehydration and desulfurization process is the glycolamine process, in which the treatment solution is a mixture of ethanolamine and a large amount of glycol. The mixture is circulated through an absorber and a reactivator in the same way as ethanolamine is circulated in the Girbotol process. The glycol absorbs moisture from the hydrocarbon gas passing up the absorber; the ethanolamine absorbs hydrogen sulfide and carbon dioxide. The treated gas leaves the top of the absorber; the spent ethanolamine-glycol mixture enters the reactivator tower, where heat drives off the absorbed acid gases and water.

Absorption occurs when the water vapor is taken out by a dehydrating agent. Adsorption occurs when the water vapor is condensed and collected on the surface. In a majority of cases, cooling alone is insufficient and, for the most part, impractical for use in field operations. Other more convenient water removal options use (i) *hygroscopic* liquids (e.g., diethylene glycol or triethylene glycol) and (ii) solid adsorbents or desiccants (e.g., alumina, silica gel, and molecular sieves). Ethylene glycol can be directly injected into the gas stream in refrigeration plants.

Absorption

An example of absorption dehydration is known as *glycol dehydration* – the principal agent in this process is diethylene glycol which has a chemical affinity for water. Glycol dehydration involves using a solution of a glycol such as diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the wet gas stream in a *contactor*. In practice, absorption systems recover 90 to 99% by volume of methane that would otherwise be flared into the atmosphere.

In the process, a liquid desiccant dehydrator serves to absorb water vapor from the gas stream. The glycol solution absorbs water from the wet gas, and once absorbed, the glycol particles become heavier and sink to the bottom of the contactor where they are removed. The dry gas stream is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the gas stream, is recycled through a specialized boiler designed to vaporize only the water out of the solution. The boiling point differential between water (100°C, 212°F) and glycol (204°C, 400°F) makes it relatively easy to remove water from the glycol solution.

As well as absorbing water from the wet gas stream, the glycol solution occasionally carries with it small amounts of methane and other compounds found in the wet gas. In order to decrease the amount of methane and other compounds that would otherwise be lost, flash tank separator-condensers are employed to remove these compounds before the glycol solution reaches the boiler. The flash tank separator consists of a device that reduces the pressure of the glycol solution stream, allowing the methane and other hydrocarbon derivatives to vaporize (*flash*). The glycol solution then travels to the boiler, which may also be fitted with air- or water-cooled condensers, which serve to capture any remaining organic compounds that may remain in the glycol solution. The regeneration (stripping) of the glycol is limited by temperature: diethylene glycol and triethylene glycol decompose at or even before their respective boiling points. Such techniques as stripping of hot triethylene glycol with dry gas (such as high-boiling hydrocarbon vapors, the *Drizo process*) or vacuum distillation are recommended.

Another absorption process, the Rectisol process, is a physical acid gas removal process using an organic solvent (typically methanol) at subzero temperatures, and characteristic of physical acid gas removal processes, it can purify a gas stream down to 0.1 ppm v/v total sulfur, including hydrogen sulfide (H_2S) and carbonyl sulfide (COS), and carbon dioxide (CO_2) in the ppm v/v range. The process uses methanol as a wash solvent, and the wash unit operates under favorable at temperatures below 0°C (32°F). To lower the temperature of the feed gas temperatures, it is cooled against the cold-product streams, before entering the absorber tower. At the absorber tower, carbon dioxide and hydrogen sulfide (with carbonyl sulfide) are removed. By use of an intermediate flash, co-absorbed products such as hydrogen and carbon monoxide are recovered, thus increasing the product recovery rate. To reduce the required energy demand for the carbon dioxide compressor, the carbon dioxide product is recovered in two different pressure steps (medium pressure and lower pressure). The carbon dioxide product is essentially sulfur-free (hydrogen sulfide-free, carbonyl sulfide-free) and water free. The carbon dioxide products can be used for enhanced oil recovery (EOR) and/or sequestration or as pure carbon dioxide for other processes.

Adsorption

Adsorption is a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. It must be emphasized that *adsorption* differs from *absorption* in that absorption is not a physical-chemical surface phenomenon but a process in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). Dehydration using a solid adsorbent or solid-desiccant is the primary form of dehydrating the gas stream using adsorption, and usually consists of two or more adsorption towers, which are filled with a solid desiccant. Typical desiccants include activated alumina or a granular silica gel material. A wet gas stream is passed through these towers, from top to bottom. As the wet gas passes around the particles of desiccant material, water is retained on the surface of these desiccant particles. Passing through the entire desiccant bed, almost all of the water is adsorbed onto the desiccant material, leaving the dry gas to exit the bottom of the tower. There are several solid desiccants which possess the physical characteristic to adsorb water from the gas stream. These desiccants are generally used in dehydration systems consisting of two or more towers and associated regeneration equipment.

Molecular sieves – a class of aluminosilicates which produce the lowest water dew points and which can be used to simultaneously sweeten, dry gases and liquids – are commonly used in dehydrators ahead of plants designed to recover ethane and other higher-boiling hydrocarbon derivatives. These plants operate at very cold temperatures and require very dry feed gas to prevent formation of hydrates. Dehydration to -100°C (-148°F) dew point is possible with molecular sieves. Water dew points less than -100°C (-148°F) can be accomplished with special design and definitive operating parameters.

Molecular sieves are commonly used to selectively adsorb water and sulfur compounds from low-boiling hydrocarbon streams such as liquefied petroleum gas, propane, butane, pentane, low-boiling olefin derivatives, and alkylation feed. Sulfur compounds that can be removed are hydrogen sulfide, mercaptan derivatives, sulfide derivatives, and disulfide derivatives. In the process, the sulfur-containing feedstock is passed through a bed of sieves at ambient temperature. The operating pressure must be high enough to keep the feed in the liquid phase. The operation is cyclic in that the adsorption step is stopped at a predetermined time before sulfur breakthrough occurs. Sulfur and water are removed from the sieves by purging with fuel gas at 205 to 315°C (400 to 600°F).

Solid-adsorbent dehydrators are typically more effective than liquid absorption dehydrators (e.g., glycol dehydrators) and are usually installed as a type of straddle system along gas pipelines. These types of dehydration systems are best suited for large volumes of gas under high pressure, and are thus usually located on a pipeline

downstream of a compressor station. Two or more towers are required due to the fact that after a certain period of use, the desiccant in a particular tower becomes saturated with water. To regenerate and recycle the desiccant, a high-temperature heater is used to heat gas to a high temperature and passage of the heated gas stream through a saturated desiccant bed vaporizes the water in the desiccant tower, leaving it dry and allowing for further dehydration of the gas stream.

Although two-bed adsorbent treaters have become more common (while one bed is removing water from the gas, the other undergoes alternate heating and cooling), on occasion, a three-bed system is used: one bed adsorbs, one is being heated, and one is being cooled. An additional advantage of the three-bed system is the facile conversion of a two-bed system so that the third bed can be maintained or replaced, thereby ensuring continuity of the operations and reducing the risk of a costly plant shutdown.

Silica gel (SiO_2) and alumina (Al_2O_3) have good capacities for water adsorption (up to 8% by weight). Bauxite (crude alumina, Al_2O_3) adsorbs up to 6% by weight water, and molecular sieves adsorb up to 15% by weight water. Silica is usually selected for dehydration of sour gas because of its high tolerance to hydrogen sulfide and to protect molecular sieve beds from plugging by sulfur. Alumina *guard beds* serve as protectors by the act of attrition and may be referred to as an *attrition reactor* containing an *attrition catalyst* may be placed ahead of the molecular sieves to remove the sulfur compounds. Downflow reactors are commonly used for adsorption processes, with an upward flow regeneration of the adsorbent and cooling using gas flow in the same direction as adsorption flow.

Solid desiccant units generally cost more to buy and operate than glycol units. Therefore, their use is typically limited to applications such as gases having a high hydrogen sulfide content, low dew point requirements, simultaneous control of water, and hydrocarbon dew points. In processes where cryogenic temperatures are encountered, solid desiccant dehydration is usually preferred over conventional methanol injection to prevent hydrate and ice formation.

Cryogenics

Another possibility for drying a gas stream is by cooling the gas in electrically powered gas coolers, at temperatures below 10°C (50°F), which allows a lot of humidity to be removed. In order to minimize the relative humidity, but not the absolute humidity, the gas can be warmed up again after cooling, in order to prevent condensation along the gas pipelines.

Thus, cryogenic upgrading makes use of the distinct boiling/sublimation points of the different gases, particularly for the separation of carbon dioxide and methane. In the process, the raw (untreated) gas stream is cooled down to the temperatures where the carbon dioxide in the gas condenses or sublimates and can be separated as a liquid or a solid fraction, while methane accumulates in the gas phase. Water and siloxane derivatives are also removed during cooling of the gas. However, the content of methane in the gas stream affects the characteristics of the gas, i.e., higher pressures and/or lower temperatures are needed to condense or sublime carbon dioxide when it is in a mixture with methane. Cooling usually takes place in several steps in order to remove the different gases in the gas stream individually and to optimize the energy recovery.

As an example, a hot gas stream containing water and carbon dioxide can be upgraded; by cooling the gas to 40°C (104°F), most of the water is condensed. The remaining water is removed in the carbon dioxide removal step – the carbon dioxide to be removed from the gas stream to meet the specifications. The final concentration of carbon dioxide in the gas stream is determined by the specification of the Wobbe index. For carbon dioxide removal, considering the high partial pressure of carbon dioxide, both membranes and physical solvents can be chosen, where membranes are at their maximum scale and physical solvents are at their minimum scale. The main advantage of the cryogenic process is that it is possible to obtain a gas stream with high methane content of up to 99% v/v. The main disadvantage is that the upgrading process is necessary to use many of technological equipment, especially compressors, turbines, and heat exchangers. This significant demand for additional equipment can make the cryogenic separation process extremely expensive.

Methanol-Based Processes

Methanol is probably one of the most versatile solvents in the gas processing industry. Historically, methanol was the first commercial organic physical solvent and has been used for dehydration, hydrate inhibition, gas sweetening,

and liquids recovery. Most of these applications involve low temperature where the physical properties of methanol are advantageous compared with other solvents that exhibit high viscosity problems or even solids formation. Operation at low temperatures tends to suppress the most significant disadvantage of methanol – i.e., high solvent loss. Furthermore, methanol is relatively inexpensive and easy to produce, making the solvent an attractive alternate for gas processing applications.

The use of methanol has been further exploited in the development of the Rectisol process, either alone or as toluene-methanol mixtures are used to remove hydrogen sulfide more selectively and direct the carbon dioxide to the overhead product. Toluene has an additional advantage insofar as carbonyl sulfide (carbonyl sulfide) is more soluble in toluene than in methanol. The Rectisol process was primarily developed to remove both carbon dioxide and hydrogen sulfide (along with other sulfur-containing species) from gas streams resulting from the partial oxidation of coal, oil, and crude oil residues. The ability of methanol to absorb these unwanted components made it the natural solvent of choice. Unfortunately, at cold temperatures, methanol also has a high affinity for hydrocarbon constituents of the gas streams. For example, propane is more soluble in methanol than is carbon dioxide. There are two versions of the Rectisol process – the two-stage and the once-through. The first step of the two-stage process is desulfurization before shift conversion; the concentrations of hydrogen sulfide and carbon dioxide are approximately 1 and 5% v/v, respectively. Regeneration of the methanol following the desulfurization of the feed gas produces high sulfur feed for sulfur recovery. The once-through process is only applicable for high pressure partial oxidation products. The once-through process is also applicable when the hydrogen sulfide to carbon dioxide content is unfavorable, in the neighborhood of 1:50.

Recently, a process using methanol has been developed in which it has the simultaneous capability to dehydrate, to remove acid gas, and to control hydrocarbon dew point. The IFPEXOL-1 is used for water removal and hydrocarbon dew point control; the IFPEXOL-2 process is used for acid gas removal. The novel concept behind the IFPEXOL-1 process is to use a portion of the water-saturated inlet feed to recover the methanol from the aqueous portion of the low temperature separator. That approach has solved a major problem with methanol injection in large facilities, the methanol recovery via distillation. Beyond that discovery, the cold section of the process is remarkably similar to a basic methanol injection process. Modifications to the process include water washing the hydrocarbon liquid from the low temperature separator to enhance the methanol recovery. The IFPEXOL-2 process for acid gas removal is similar to an amine-type process except for the operating temperatures. The absorber operates below -20°F to minimize methanol losses, and the regenerator operates at approximately 90 psi. Cooling is required on the regenerator condenser to recover the methanol. This process usually follows the IFPEXOL-1 process, so excessive hydrocarbon absorption is not as great a problem.

Gas Compression

Compression is used in all aspects of the gas industry, and the benefits of operating at higher pressures include the ability to transmit larger volumes of gas through a given size of pipeline, lower transmission losses due to friction, and the capability to transmit gas over long distances without additional boosting stations. In gas transmission, two basic types of compressors are used: reciprocating and centrifugal compressors. Reciprocating compressors are usually driven by either electric motors or gas engines, whereas centrifugal compressors use gas turbines or electric motors as drivers.

The key variables for equipment selections are life cycle cost, capital cost, maintenance costs, including overhaul and spare parts, fuel, or energy costs. The units' level of utilization, as well as demand fluctuations, plays an important role. While both gas engines and gas turbines can use pipeline gas as a fuel, an electric motor has to rely on the availability of electric power. Due to the number of variables involved, the task of choosing the optimum driver can be quite involved, and a comparison between the different types of drivers should be done before a final selection is made.

The task of gas compression is to bring gas from a certain suction pressure to a higher discharge pressure by means of mechanical work. The actual compression process is often compared to one of three ideal processes: isothermal, isentropic, and polytropic compression.

Isothermal compression occurs when the temperature is kept constant during the compression process. It is not adiabatic because the heat generated in the compression process has to be removed from the system. The compression process is isentropic or adiabatic reversible if no heat is added to or removed from the gas during compression, and the process is frictionless. With these assumptions, the entropy of the gas does not change during the compression process. The polytropic compression process is like the isentropic cycle reversible, but it is not adiabatic. It can be described as an infinite number of isentropic steps, each interrupted by isobaric heat transfer. This heat addition guarantees that the process will yield the same discharge temperature as the real process.

Gas Condensate

Gas condensate (sometimes referred to as *condensate*) is a term that has its roots in the natural gas industry and refers to a mixture of low-boiling hydrocarbon liquids obtained by condensation of the vapors of these hydrocarbon constituents, either in the well or as the gas stream emits from the well. In fact, the term can be applied to any gas stream that contains low-boiling hydrocarbon liquids that are obtained by condensation of the vapors of these hydrocarbon constituents.

The condensate is typically pentane (C_5H_{12}) with varying amounts of higher-boiling hydrocarbon derivatives (up to C_8H_{18}), but relatively little methane or ethane; propane (C_3H_8) butane (C_4H_{10}) may be present in condensate by dissolution in the liquids. Depending upon the source of the condensate, benzene (C_6H_6), toluene ($C_6H_5CH_3$), xylene isomers ($CH_3C_6H_4CH_3$), and ethyl benzene ($C_6H_5C_2H_5$) may also be present. Typically, the condensate is a colorless to straw-yellow water-like fluid with an objectionable odor if hydrogen sulfide is present.

The terms *condensate* and *distillate* are often used interchangeably to describe the liquid produced in tanks, but each term stands for a different material. Along with large volumes of gas, some wells produce a water-white or light straw-colored liquid that resembles low-boiling naphtha. The liquid has been called *distillate* because it resembles the products obtained from crude oil in refineries by distilling the volatile components from crude oil.

The knowledge of the phase behavior of gas-condensates is important for the prediction of the behavior of the gas stream, especially during transportation of the gas (when liquid dropout may occur) and during gas clearing. Liquid dropout typically occurs when there is pressure reduction.

Gas-Cooled Reactor

A gas-cooled reactor is a nuclear reactor that uses graphite as a neutron moderator and carbon dioxide as a coolant. Gas-cooled reactors are advanced carbon-dioxide gas cooled reactors – the advanced high-temperature gas-cooled reactors use helium as a coolant and can achieve high fuel utilization rates and operate at high temperatures. They also produce process heat, which can be used for hydrogen production and low-temperature applications such as seawater desalination and district heating.

The gas-cooled fast reactor system is a nuclear reactor design that features a fast neutron spectrum and a closed fuel cycle for efficient conversion of uranium and management of actinides. The reference reactor design is a helium-cooled system operating with an outlet temperature of 850°C (1,560°F) using a direct closed-cycle turbine for high thermal efficiency. Several fuel forms are available for their potential to operate at high temperatures and to ensure an excellent retention of fission products composite ceramic fuel, advanced fuel particles, or ceramic clad elements of actinide compounds. Core configurations are being considered based on pin- or plate-based fuel assemblies or prismatic blocks, which allows for better coolant circulation than traditional fuel assemblies.

The gas-cooled reactor fast reactor operates on fast neutrons; no moderator is needed to slow neutrons down. This means that, apart from nuclear fuel such as uranium, other fuels can be used. The most common is thorium, which absorbs a fast neutron and decays into uranium-233 (^{233}U). This means gas-cooled fast reactor designs have

breeding properties—they can use fuel that is unsuitable in light water reactor designs and breed fuel. Because of these properties, once the initial loading of fuel has been applied into the reactor, the unit can go years without needing fuel. If these reactors are used for breeding, it is economical to remove the fuel and separate the generated fuel for future use.

The reactors are intended for use in nuclear power plants to produce electricity, while at the same time producing (breeding) new nuclear fuel.

See: Nuclear Reactor – Gas-Cooled Reactor.

Gaseous Effluents

Gaseous effluents from refining processes can be valuable products, or they can create a number of environmental problems. During combustion, the combination of hydrocarbon derivatives, nitrogen oxide, and sunlight results in localized low-levels of ozone, or smog. This is particularly evident in large urban areas and especially when air does not circulate well. The use of crude oil products in various vehicles also contributes to the problem in many areas. The primary effects are on the health of those exposed to the ozone, but plant life has been observed to suffer as well.

Refinery gas and other gas streams may contain large amounts of acid gases, such as hydrogen sulfide (H_2S) and carbon dioxide (CO_2). Hydrogen chloride (HCl), although not usually considered to be a major pollutant in crude oil refineries, can arise during processing from the presence of brine in crude oil that is incompletely dried. It can also be produced from mineral matter and other inorganic contaminants and is gaining increasing recognition as a pollutant which needs serious attention.

Acid gases corrode refining equipment, harm catalysts, pollute the atmosphere, and prevent the use of hydrocarbon components in petrochemical manufacture. When the amount of hydrogen sulfide is large, it may be removed from a gas stream and converted to sulfur or sulfuric acid. Some gases contain sufficient carbon dioxide to warrant recovery as dry ice, i.e., solid carbon dioxide. And there is now a conscientious effort to mitigate the emission of pollutants from hydrotreating process by careful selection of process parameters and catalysts.

The terms refinery gas and process gas are also often used to include all of the gaseous products and by-products that emanate from a variety of refinery processes. There are also components of the gaseous products that must be removed prior to release of the gases to the atmosphere or prior to use of the gas in another part of the refinery, i.e., as a fuel gas or as a process feedstock.

Crude oil refining produces gas streams often contain substantial amounts of acid gases such as hydrogen sulfide and carbon dioxide. More particularly, hydrogen sulfide arises from the hydrosulfurization of feedstocks that contain organic sulfur:

Crude oil refining involves, with the exception of some of the more viscous crude oils, a primary distillation of the hydrogen mixture, which results in its separation into fractions differing in carbon number, volatility, specific gravity, and other characteristics. The most volatile fraction, that contains most of the gases which are generally dissolved in the crude, is referred to as pipe still gas or pipe still light ends and consists essentially of hydrocarbon gases ranging from methane to butane(s), or sometimes pentane(s).

The gas varies in composition and volume, depending on crude origin and on any additions to the crude made at the loading point. It is not uncommon to re-inject low-boiling hydrocarbon derivatives such as propane and butane into the crude before dispatch by tanker or pipeline. This results in a higher vapor pressure of the crude, but it allows one to increase the quantity of low-boiling products obtained at the refinery. Since light ends in most crude oil markets command a premium, while in the oil field itself propane and butane may have to be re-injected or flared, the practice of spiking crude oil with liquefied petroleum gas is becoming fairly common.

In addition to the gases obtained by distillation of crude oil, more highly volatile products result from the subsequent processing of naphtha and middle distillate to produce gasoline. Hydrogen sulfide is produced in the desulfurization processes involving hydrogen treatment of naphtha, distillate, and residual fuel, and from the

coking or similar thermal treatments of vacuum gas oils and residual fuels. The most common processing step in the production of gasoline is the catalytic reforming of hydrocarbon fractions in the heptane (C_7) to decane (C_{10}) range.

In a series of processes commercialized under the generic name reforming, paraffin and naphthene (cyclic non-aromatic) hydrocarbon derivatives, are altered structurally in the presence of hydrogen and a catalyst into aromatics, or isomerized to more highly branched hydrocarbon derivatives. Catalytic reforming processes thus not only result in the formation of a liquid product of higher octane number, but also produce substantial quantities of gases. The latter are rich in hydrogen, but also contain hydrocarbon derivatives from methane to butanes, with a preponderance of propane ($CH_3CH_2CH_3$), n-butane ($CH_3CH_2CH_2CH_3$), and iso-butane [$(CH_3)_3CH$].

The composition of the process gases varies in accordance with reforming severity and reformer feedstock. All catalytic reforming processes require substantial recycling of a hydrogen stream. Therefore, it is normal to separate reformer gas into a propane ($CH_3CH_2CH_3$) and/or a butane stream [$CH_3CH_2CH_2CH_3$ plus $(CH_3)_3CH$], which becomes part of the refinery liquefied petroleum gas production, and a lower-boiling gas fraction, part of which is recycled. In view of the excess of hydrogen in the gas, all products of catalytic reforming are saturated, and there are usually no olefin gases present in either gas stream.

A second group of refining operations that contributes to gas production is that of the catalytic cracking processes. These consist of fluid-bed catalytic cracking in which high-boiling gas oils are converted into gas, liquefied petroleum gas, catalytic naphtha, fuel oil, and coke by contacting the high-boiling feedstock with the hot catalyst. Both catalytic and thermal cracking processes, the latter being now largely used for the production of chemical raw materials, result in the formation of unsaturated hydrocarbon derivatives, particularly ethylene ($CH_2=CH_2$), but also propylene (propene, $CH_3CH=CH_2$), iso-butylene [iso-butene, $(CH_3)_2C=CH_2$] and the n-butenes ($CH_3CH_2CH=CH_2$, and $CH_3CH=CHCH_3$) in addition to hydrogen (H_2), methane (CH_4) and smaller quantities of ethane (CH_3CH_3), propane ($CH_3CH_2CH_3$), and butanes [$CH_3CH_2CH_2CH_3$, $(CH_3)_3CH$]. Diolefins such as butadiene ($CH_2=CHCH=CH_2$) are also present.

Additional gases are produced in refineries with visbreaking and/or coking facilities that are used to process of the heaviest crude fractions. In the visbreaking process, fuel oil is passed through externally fired tubes and undergoes liquid-phase cracking reactions, which result in the formation of lower-boiling fuel oil components. Oil viscosity is thereby reduced, and some gases, mainly hydrogen, methane, and ethane, are formed. Substantial quantities of both gas and carbon are also formed in coking (both delayed coking and fluid coking) in addition to the middle distillate and naphtha. When coking a residual fuel oil or high-boiling gas oil, the feedstock is preheated and contacted with hot carbon (coke) which causes extensive cracking of the feedstock constituents of higher molecular weight to produce lower-molecular-weight products ranging from methane, via liquefied petroleum gas and naphtha, to gas oil and heating oil. Products from coking processes tend to be unsaturated, and olefin components predominate in the tail gases from coking processes.

A further source of refinery gas is hydrocracking, a catalytic high-pressure pyrolysis process in the presence of fresh and recycled hydrogen. The feedstock is again high-boiling gas oil or residual fuel oil, and the process is directed mainly at the production of additional middle distillates and gasoline. Since hydrogen is to be recycled, the gases produced in this process again have to be separated into lower-boiling and higher-boiling streams; any surplus recycle gas and the liquefied petroleum gas from the hydrocracking process are both saturated.

Both hydrocracker gases and catalytic reformer gases are commonly used in catalytic desulfurization processes. In the latter, feedstocks ranging from lower-boiling gas oil to vacuum gas oil are passed at pressures of 500 to 1,000 psi (3.5 to 7.0×10^3 kPa) with hydrogen over a hydrofining catalyst. This results mainly in the conversion of organic sulfur compounds to hydrogen sulfide,

The reaction also produces some low-boiling hydrocarbon derivatives by hydrocracking.

Thus refinery streams, while ostensibly being hydrocarbon in nature, may contain large amounts of acid gases such as hydrogen sulfide and carbon dioxide. Most commercial plants employ hydrogenation to convert organic

sulfur compounds into hydrogen sulfide. Hydrogenation is effected by means of recycled hydrogen-containing gases or external hydrogen over a nickel molybdate or cobalt molybdate catalyst.

In summary, refinery process gas, in addition to hydrocarbon derivatives, may contain other contaminants, such as carbon oxides (CO_x , where $x = 1$ and/or 2), sulfur oxides (SO_x , where $x = 2$ and/or 3), as well as ammonia (NH_3), mercaptans (R-SH), and carbonyl sulfide (COS).

The presence of these impurities may eliminate some of the sweetening processes, since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes not designed to remove (or incapable of removing) large amounts of acid gases whereas they are capable of removing the acid gas impurities to low levels when the acid gases are present only in low-to-medium concentration in the gas.

From an environmental viewpoint, it is not the means by which these gases can be utilized but it is the effects of these gases on the environment when they are introduced into the atmosphere. In addition to the corrosion of equipment of acid gases, the escape into the atmosphere of sulfur-containing gases can eventually lead to the formation of the constituents of acid rain, i.e., the oxides of sulfur (SO_2 and SO_3). Similarly, the nitrogen-containing gases can also lead to nitrous and nitric acids (through the formation of the oxides of nitrogen (NO_x , where $x = 1$ or 2) which are the other major contributors to acid rain. The release of carbon dioxide and hydrocarbon derivatives as constituents of refinery effluents can also influence the behavior and integrity of the ozone layer.

Hydrogen chloride, if produced during refining, quickly picks up moisture in the atmosphere to form droplets of hydrochloric acid and, like sulfur dioxide, is a contributor to acid rain. However, hydrogen chloride may exert severe local effects because, unlike sulfur dioxide, it does not need to participate in any further chemical reaction to become an acid and. Under atmospheric conditions that favor a buildup of stack emissions in the area of a large industrial complex or power plant, the amount of hydrochloric acid in rainwater could be quite high.

Any gas stream is also capable of producing emissions that are detrimental to the environment. For example, constituents such as carbon dioxide (CO), hydrogen sulfide (H_2S), and mercaptans (thiols; R-SH), as well as trace amounts of sundry other emissions can cause considerable harm to the environment. Any removal process must be very precise, since the gas stream may contain only a small quantity of harmful constituents that must be reduced by several orders of magnitude.

It is generally believed (the chemical thermodynamics are favorable) that acidic compounds are formed when sulfur dioxide and nitrogen oxide emissions are released from tall industrial stacks. Gases such as sulfur oxides (usually sulfur dioxide, SO_2) as well as the nitrogen oxides (NO_x) react with the water in the atmosphere to form acids:

Acid rain has a pH less than 5.0 and predominantly consists of sulfuric acid (H_2SO_4) and nitric acid (HNO_3). As a point of reference, in the absence of anthropogenic pollution sources the average pH of rain is approximately 6.0 (slightly acidic; neutral pH = 7.0). In summary, the sulfur dioxide that is produced during a variety of processes will react with oxygen and water in the atmosphere to yield environmentally detrimental sulfuric acid. Similarly, nitrogen oxides will also react to produce nitric acid.

Another acid gas, hydrogen chloride (HCl), although not usually considered to be a major emission, is produced from mineral matter and the brines that often accompany crude oil during production and is gaining increasing

recognition as a contributor to acid rain. However, hydrogen chloride may exert severe local effects because it does not need to participate in any further chemical reaction to become an acid. Under atmospheric conditions that favor a buildup of stack emissions in the areas where hydrogen chloride is produced, the amount of hydrochloric acid in rainwater could be quite high.

In addition to hydrogen sulfide and carbon dioxide, gas may contain other contaminants, such as mercaptans (R-SH) and carbonyl sulfide (COS). The presence of these impurities may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. However, these processes are also capable of removing the acid gas impurities to low levels when the acid gases are there in low-to-medium concentrations in the gas.

On a regional level the emission of sulfur oxides (SO_x) and nitrogen oxides (NO_x) can also cause the formation of acid species at high altitudes, which eventually precipitate in the form of acid rain, damaging plants, wildlife, and property. At the global level, there is concern that the increased use of hydrocarbon-based fuels will ultimately raise the temperature of the planet (global warming), as carbon dioxide reflects the infrared or thermal emissions from the earth, preventing them from escaping into space (greenhouse effect). Whether or not the potential for global warming becomes real will depend upon how emissions into the atmosphere are handled. There is considerable discussion related to the merits and the de-merits of the global warming theory and the discussion is likely to continue for some time. Be that as it may, the atmosphere can only tolerate pollutants up to a limiting value. And that value needs to be determined. In the meantime, efforts must be made to curtail the use of noxious and foreign (non-indigenous) materials into the air.

Gaseous Fuels

Gaseous fuels are those fuels that are in the gaseous state under ambient conditions (Table G-3). In some circumstances, the definition of gaseous fuels may also include the low-boiling hydrocarbons such as pentane but such fuels are considered to be liquid fuels.

Table G-3 General properties and description of gaseous fuels.

	Molecular weight	Specific gravity	Boiling	Ignition
			Point, °F	Temperature, °F
Methane	16.0	0.553	-258.7	900-1170
Ethane	30.1	0.572	-127.5	959
Ethylene	28.0		-154.7	914
Propane	44.1		-43.8	842
Propylene	42.1		-53.9	856
n-Butane	58.1	0.601	31.1	761
iso-Butane	58.1		10.9	864
n-Butene	56.1	0.595	21.2	829
iso-Butene	56.1		19.6	869

The terminology used to describe gaseous fuels is variable (Table G-4), and sincere efforts must be made to accurately identify the gaseous fuel on the basis of type and composition.

Table G-4 Common terminology used to describe gases fuels.

Acid gas	A gas containing hydrogen sulfide (H_2S) and/or carbon dioxide (CO_2).
Biogas	A medium Btu gas containing methane and carbon dioxide, resulting from the action of microorganisms on organic materials such as a landfill.
Blue gas	A mixture consisting chiefly of carbon monoxide (CO) and hydrogen (H_2) typically formed by action of steam on hot coal or coke.
Carbon monoxide	A colorless, odorless, very toxic gas formed by incomplete combustion of carbon, as in water gas or producer gas production.
Carbureted blue gas	See Water gas.
Carbureted gas	Gas that has been passed been in contact with a liquid fuel and thereby mixing the air/gas and fuel.
Coal gas	The mixture of volatile products (mainly hydrogen, methane, carbon monoxide, and nitrogen) remaining after removal of water and tar, obtained from carbonization of coal, having a heat content on the order of 400-600 Btu/ft ³ .
Coke-oven gas	A medium-Btu gas, typically 550 Btu/ft ³ , produced as a by-product in the manufacture of coke by heating coal at moderate temperatures.
Destructive distillation	The process of pyrolysis conducted in a distillation apparatus to allow the volatile products to be collected. Sometimes referred to as cracking distillation.
Flue gas	The gas removed from a process (or process reactor or boiler) by a flue or chimney.
Gasification	A partial oxidation process that converts carbonaceous materials into a gaseous mixture of carbon monoxide and hydrogen (also known as synthesis gas) by reacting the raw material at high temperatures with controlled amounts of oxygen and/or steam.
High-Btu gas	A nitrogen-rich gas with a heat content of >800 Btu/ft ³ produced in gasification processes.
Landfill gas	Gas produced by the decay of organic matter in a landfill; often referred to as biogas.
Liquefied petroleum gas	Also known as LPG; a mixture of liquefied propane and butane.
Low-Btu gas	A nitrogen-rich gas with a heat content of 550 Btu/ft ³ produced in gasification processes using air as the source of the oxidant (oxygen); the air-blown form of producer gas.
Manufactured gas	A gas obtained by destructive distillation of coal, or by the thermal decomposition of crude oil, or by the reaction of steam passing through a bed of heated coal or coke. Examples are coal gases, coke oven gases, producer gas, blast furnace gas, blue (water) gas, and carbureted water gas. Btu content varies widely.
Medium-Btu gas	A gas with a heat content on the order of 100 to 200 Btu/ft ³ produced in gasification processes.
Producer gas	A gas mixture containing carbon monoxide (CO), hydrogen (H_2), carbon dioxide (CO_2), and nitrogen (N_2). In some countries, producer gas is a generic term referring to wood gas or town gas or syngas. The heat content may be on the order of 110-160 Btu/ft ³ (air combustion) or 400-500 Btu/ft ³ (oxygen combustion). The gas may be used to power gas turbines which are suited to fuels of low calorific value.
Pyrolysis	The thermal decomposition of organic materials by heating in the absence of oxygen or any other reagents, except possibly steam.
Refinery gas	Non-condensable gas collected in a petroleum refinery.
Stack gas	The product gas evolved during complete combustion of a fuel.
Sweetened gas	Gas from which acid (sour) gases such as hydrogen sulfide (and in some cases) carbon dioxide has been removed.
Synthetic natural gas	A pipeline-quality gas that is interchangeable with natural gas (mainly methane); also referred to as substitute natural gas.
Synthesis gas	A gas mixture that contains varying amounts of carbon monoxide (CO) and hydrogen (H_2) generated by the gasification of a carbonaceous material to a gaseous product.

(Continued)

Table G-4 Common terminology used to describe gases fuels. (*Continued*)

Tail gas	Residual gas leaving a process and not always required for further processing.
Town gas	Contains hydrogen (H ₂), carbon monoxide (CO), carbon dioxide (CO ₂), methane (CH ₄), nitrogen (N ₂), and volatile hydrocarbon derivatives. Produced by blowing air and steam over an incandescent fuel bed, usually of coke or coal; typically has a heat content on the order of 600 Btu/ft ³ .
Water gas	A mixture of carbon monoxide (CO) and hydrogen (H ₂) produced by passing steam over red-hot coke using the endothermic reaction $C + H_2O \rightarrow CO + H_2$. This product had a lower calorific value than coal gas, so the gas is often passed through a heated retort into which oil was sprayed to produce carbureted water gas; sometimes referred to as carbureted blue gas.
Wood gas	The product of thermal gasification of woody biomass (such as wood chips, wood waste, and sawdust) in a gasifier or wood gas generator. It is the result of a high temperature reaction (>700°C, 1,290°F) where the feedstock reacts with steam or a limited amount of air producing carbon monoxide (CO), carbon dioxide (CO ₂), hydrogen (H ₂), and methane (CH ₄). After the gas is filtered, purified (scrubbed), and used to power gas turbines.

Biogas is a clean and renewable form of energy, and the most important biogas components are methane (CH₄), carbon dioxide (CO₂), and sulfuric components (H₂S). The gas generally composes of methane (55 to 65%), carbon dioxide (35 to 45%), nitrogen (0 to 3%), hydrogen (0 to 1%), and hydrogen sulfide (0 to 1%).

Biogas could very well substitute for conventional sources of energy (i.e., fossil fuels) which are causing ecological–environmental problems and at the same time, depleting at a faster rate. Due to its elevated methane content, resultant of the organic degradation in the absence of molecular oxygen, biogas is an attractive source of energy. The physical, chemical, and biological characteristics of the manure are related to diet composition, which can influence the biogas composition. The biogas composition is an essential parameter because it allows identifying the appropriate purification system, which aims to remove sulfuric gases and decrease the water volume, contributing to improve the combustion fuel conditions.

Biogas production has usually been applied for waste treatment, mainly sewage sludge, agricultural waste (manure), and industrial organic waste streams. The primary source, which delivers the necessary microorganisms for biomass biodegradation and as well, one of the largest single sources of biomass from food/feed industry, is manure from animal production, mainly from cows and pig farms.

Currently, biogas production is mainly based on the anaerobic digestion of single energy crops. Maize, sunflower, grass, and Sudan grass are the most commonly used energy crops. In the future, biogas production from energy crops will increase and requires to be based on a wide range of energy crops that are grown in versatile, sustainable crop rotations.

A specific source of biogas is landfills. In a typical landfill, the continuous deposition of solid waste results in high densities and the organic content of the solid waste undergoes microbial decomposition. The production of methane-rich landfill gas from landfill sites makes a significant contribution to atmospheric methane emissions. In many situations, the collection of landfill gas and production of electricity by converting this gas in gas engines is profitable and the application of such systems has become widespread. The benefits are obvious: useful energy carriers are produced from gas that would otherwise contribute to a build-up of methane in the atmosphere, which has stronger greenhouse gas impact than the carbon dioxide emitted from the power plant. This makes landfill gas utilization in general an attractive greenhouse gas mitigation option, which is being increasingly deployed in world regions.

Generally, biogas is most commonly produced by using animal manure mixed with water, which is stirred and warned inside an airtight container, known as a digester. The most important biogas components are methane, carbon dioxide, and sulfuric components. The gas is generally composed of methane (55 to 65%), carbon dioxide (35 to 45%), nitrogen (0 to 3%), hydrogen (0 to 1%), and hydrogen sulfide (0 to 1%).

Anaerobic processes could either occur naturally or in a controlled environment such as a biogas plant. Organic waste such as livestock manure and various types of bacteria are put in an airtight container called digester so the process could occur. In the complex process of anaerobic digestion, hydrolysis/acidification and methanogenesis are considered as rate-limiting steps.

Most biomass materials are easier to gasify than coal because they are more reactive with higher ignition stability. This characteristic also makes them easier to process thermochemically into higher-value fuels such as methanol or hydrogen. Ash content is typically lower than for most coals, and sulfur content is much lower than for many fossil fuels. Unlike coal ash, which may contain toxic metals and other trace contaminants, biomass ash may be used as a

soil amendment to help replenish nutrients removed by harvest. A few biomass feedstocks stand out for their peculiar properties, such as high silicon or alkali metal contents – these may require special precautions for harvesting, processing, and combustion equipment. Note also that mineral content can vary as a function of soil type and the timing of feedstock harvest. In contrast to their fairly uniform physical properties, biomass fuels are rather heterogeneous with respect to their chemical elemental composition.

A number of processes allow biomass to be transformed into gaseous fuels such as methane or hydrogen. One pathway uses algae and bacteria that have been genetically modified to produce hydrogen directly instead of the conventional biological energy carriers. Problems are intermittent production, low efficiency, and difficulty in constructing hydrogen collection and transport channels of low cost. A second pathway uses plant material such as agricultural residues in a fermentation process leading to biogas from which the desired fuels can be isolated. This technology is established and in widespread use for waste treatment, but often with the energy produced only for onsite use, which often implies less than maximum energy yields. Finally, high-temperature gasification supplies a crude gas, which may be transformed into hydrogen by a second reaction step. In addition to biogas, there is also the possibility of using the solid by-product as a biofuel.

The technologies for gas production from biomass include processes such as (i) fermentation, (ii) gasification, and (iii) direct biophotolysis.

See also: Aerobic Digestion, Anaerobic Digestion, Biofuels, Biomass, Natural Gas.

Gaseous Fuels from Waste

There are two ways of producing gaseous fuel from waste, and these are (i) gasification of the waste at high temperatures by partial oxidation and then conversion of materials containing carbon into synthesis gas (mainly hydrogen and carbon monoxide) and (ii) production of biogas, mainly methane, by the anaerobic digestion of waste.

Gasification is the general term used for processes where heat is used to transform a feedstock, usually a solid feedstock such as coal or biomass applicable to the conversion of any solid carbonaceous waste to a clean burning gaseous fuel. Whether starting with coffee grounds, municipal trash, or junk tires, the end product is a flexible gaseous fuel, and with the relevant process modifications, production of liquid and solid fuels is also possible.

Biochemical conversion options can be divided into digestion (production of biogas, a mixture of mainly methane and carbon dioxide) and fermentation (production of ethanol). With respect to thermochemical conversion options, a distinction can be made between combustion, gasification, and pyrolysis.

Anaerobic digestion is a process whereby organic waste is broken down in a controlled, oxygen-free environment by bacteria naturally occurring in the waste material. Methane rich biogas is produced, thus facilitating renewable energy generation. As a result, materials that are currently going to landfill can be utilized; natural methane emissions are reduced, and conventional generation with its associated carbon emissions is displaced. The residual nutrient-rich liquor and digestate are suitable for use as fertilizer on the farmland surrounding such a plant, reducing the need for artificial fertilizer. In summary, anaerobic digestion is a form of composting.

While solid wastes were somewhat in focus for the gasification and pyrolysis activities, around 1970, biomass gasification took over the central role when the oil prices went up after 1973.

The principle behind waste gasification and the production of gaseous fuels is that that waste contains carbon, and it is this carbon that is converted to gaseous products via the usual gasification chemistry. Thus, when fuel is fed to a gasifier, water and volatile matter are released fast and a char residue is left to react further. The char gasification is what mainly controls the conversion achieved in the process. From solid carbon, product gas is formed according to the following main reactions:

In addition to the reactions of solid carbon, the most important reaction is the water-gas-shift reaction, which takes place in the gas phase:

The product gas generally contains large amounts of hydrogen and carbon monoxide and a small amount of methane, as well as carbon dioxide and steam, and in air gasification nitrogen. In addition, a significant amount of other organic components in the gas, known as tar, is formed. Tar formation can also be anticipated to form in the gasification or pyrolysis of any complex carbonaceous material.

Biomass-based fuels (and many components of domestic and industrial waste can be included in this category) are non-fossil fuels. Vegetative biomass can be classified into the categories woody, herbaceous, agricultural by-products, energy crops, and black liquor (a by-product of the forest industry. Because of the high concentration of organic materials in industrial waste and in domestic waste (including discarded food), many constituents of waste are actually biomass. But the issues arise from the other constituents of the waste that make the waste truly heterogeneous and, in many cases, of indeterminate composition.

See also: Gaseous Fuels (Volume 3: Coal), Gasification, Gasification (Volume 3: Coal).

Gaseous Fuels from Waste – Reactors

Most of the reactors were of the fixed-bed type (updraft or downdraft) and are considered to be adequate processes for local use in terms of the alternate, i.e., landfilling the waste. However, whether wastes should be handled locally or in a large scale, centralized units is another issue that is still under debate.

Thus, a process for waste gasification must be chosen to reflect the character of the waste relation to the main questions in this report as stated in the introduction. However, few of the original processes touted as potential methods for waste gasification may not be in current commercial use and reference must be made to gasification processes (for coal) that are in current commercial use.

Processes proposed for waste gasification should include a separation step. Feedstock homogeneity is a pre-requisite for many gasifiers, and feedstock heterogeneity and process scale-up can lead to a number of mechanical problems, shut-downs, sintering, and hot spots leading to corrosion and eventual failure of the reactor wall. In addition, the heterogeneity of the non-carbon constituents of the waste and their influence on the process chemistry are often difficult to estimate.

Most of these process efforts included use of a fixed-bed reactor on the basis of applicability of coal gasification is also applicable to waste. The most common equipment was a shaft reactor with a bottom temperature of approximately 1,000°C (1,830°F) leading to transport problems within the reactor bed and in the shaft to the ash outlet, such as ash sintering. The character of coal ash and its effect on gasification is well understood. The effect of ash from waste is not yet fully understood and requires extra effort before a suitable reactor can be proposed for waste gasification.

Finally, most of the systems proposed for waste gasification produced tar or a mixture of tar and gas and very few of the processes included gas cleaning. Thus, the tar-rich gas caused problems on the gas side as well as tar condensation in the pipes to the combustor. On the other hand, waste that contained metals, glass, and inorganic materials which sinter and melt at higher temperatures also caused reactor problems.

Overall, the heterogeneous composition of domestic and industrial waste has not been beneficial in terms of the gasification of the waste. Recycling programs in which the first is first separated into various components may be a necessary prelude to waste gasification. With energy prices (crude oil and natural gas) currently at an all-time high, and threatening to continue at high levels for the foreseeable future, the time is now for development of waste gasification processes.

Gaseous Fuels from Wood

Wood can be used to make both liquid and gaseous fuels. When wood is heated in the absence of air, or with a reduced air supply, it is possible to produce a liquid fuel which can be used in a similar way to conventional oil fuels.

It can be used to run internal combustion engines in vehicles or generators. The gas produced from wood is a mixture of hydrogen and carbon monoxide which can be used in internal combustion engines or in gas turbines which can be used to power generators. Although the liquid fuels are rarely produced from wood at present, wood gas is important in other countries for producing electricity in more remote areas.

Thus, gasification technology is an attractive route for the production of fuel gases from biomass. By gasification, solid biomass is converted into a combustible gas mixture normally called producer gas consisting primarily of hydrogen (H_2) and carbon monoxide (CO), with lesser amounts of carbon dioxide (CO_2), water (H_2O), methane (CH_4), and higher hydrocarbons (C_xH_y), as well as nitrogen (N_2) and particulates.

The gasification is carried out at elevated temperatures, 500°C and 1,500°C and at atmospheric or elevated pressures. The process involves conversion of biomass, which is carried out in absence of air or with less air than the stoichiometric requirement of air for complete combustion. Partial combustion produces carbon monoxide as well as hydrogen which are both combustible gases. Solid biomass fuels, which are usually inconvenient and have low efficiency of utilization, can be converted into gaseous fuel. The energy in producer gas is 70% to 80% of the energy originally stored in the biomass. The producer gas can serve in different ways: it can be burned directly to produce heat or used as a fuel for gas engines and gas turbines to generate electricity; in addition, it can also be used as a feedstock (syngas) in the production of chemicals, e.g., methanol. The diversified applications of the producer gas make the gasification technology attractive.

A variety of biomass gasifiers has been developed and can be grouped into four major classes which are (i) the fixed-bed updraft or countercurrent gasifier, (ii) the fixed-bed downdraft or co-current gasifier, (iii) the bubbling fluidized-bed gasifier, and (iv) the circulating fluidized bed gasifier. Differentiation is based on the means of supporting the biomass in the reactor vessel, the direction of flow of both the biomass and oxidant, and the way heat is supplied to the reactor. The processes occurring in any gasifier include drying, pyrolysis, reduction, and oxidation. The unique feature of the updraft gasifier is the sequential occurrence of these processes: they are separated spatially and therefore temporally.

Using the updraft gasifier as an example, biomass and air are fed in an opposite direction. In the highest zone, biomass is heated up and releases its moisture. In the pyrolysis zone, biomass undergoes a further increase in temperature and decomposes into hydrocarbons, gas products, and char in the temperature range of 150°C to 500°C. The major reactions are:

The hydrocarbon fraction consists of methane to high boiling tar. The composition of this fraction can be influenced by many parameters, such as particle size of the biomass, temperature, pressure, heating rate, residence time, and catalysts. The operative reactions are:

The composition of the producer gases varies widely with the properties of the biomass, the gasifying agent, and the process conditions. Depending on the nature of the raw solid feedstock and the process conditions, the char formed from pyrolysis contains 20% to 60% of the energy input. Therefore, the gasification of char is an important step for the complete conversion of the solid biomass into gaseous products and for an efficient utilization of the energy in the biomass.

The producer gases from the reduction zone rise beyond the reduction zone. When they come into contact with the cooler biomass, the temperature drops down and the aforementioned reactions are frozen. The unreacted char further undergoes the oxidation with air in the lowest zone:

As a result, ash is left at the bottom of the reactor. The produced carbon dioxide flows upward and is involved in the reactions in the reduction zone. The heat released in the oxidation zone drives both the reduction and pyrolysis processes.

Gaseous Fuels – High Btu Gas

High Btu gas (high heat-content gas) is essentially pure methane and often referred to as synthetic natural gas or substitute natural gas (SNG). However, to qualify as substitute natural gas, a product must contain at least 95% v/v methane, giving an energy content (heat content) of synthetic natural gas on the order of 980 to 1,080 Btu/ft³.

The commonly accepted approach to the synthesis of high heat-content gas is the catalytic reaction of hydrogen and carbon monoxide:

To avoid catalyst poisoning, the feed gases for this reaction must be quite pure and, therefore, impurities in the product are rare. The large quantities of water produced are removed by condensation and recirculated as very pure water through the gasification system. The hydrogen is usually present in slight excess to ensure that the toxic carbon monoxide is reacted; this small quantity of hydrogen will lower the heat content to a small degree.

The carbon monoxide/hydrogen reaction is somewhat inefficient as a means of producing methane because the reaction liberates large quantities of heat. In addition, the methanation catalyst is troublesome and prone to poisoning by sulfur compounds and the decomposition of metals can destroy the catalyst. Hydrogasification may be thus employed to minimize the need for methanation:

The product of hydrogasification is far from pure methane, and additional methanation is required after hydrogen sulfide and other impurities are removed.

See also: Gaseous Fuels.

Gas Fuels – Low Btu Gas

Low Btu gas (low heat content gas) is produced during the process by oxidation of the feedstock with air; the oxygen is not separated from the air, and, as a result, the gas product invariably has a low heat-content (150 to 300 Btu/ft³). Low heat-content gas contains several components, four of which are always major components present at levels of at least several percent; a fifth component, methane, is marginally a major component.

The nitrogen content of low heat-content gas ranges from somewhat less than 33% v/v to slightly more than 50% v/v and cannot be removed by any reasonable means; the presence of nitrogen at these levels makes the product gas *low heat-content* by definition. The nitrogen also strongly limits the applicability of the gas to chemical synthesis. Two other noncombustible components (water, H₂O, and carbon dioxide, CO₂) further lower the heating value of the gas; water can be removed by condensation and carbon dioxide by relatively straightforward chemical means.

The two major combustible components are hydrogen and carbon monoxide; the H₂/CO ratio varies from approximately 2:3 to approximately 3:2. Methane may also make an appreciable contribution to the heat content of the gas. Of the minor components, hydrogen sulfide is the most significant and the amount produced is, in fact, proportional to the sulfur content of the feed coal. Any hydrogen sulfide present must be removed by one, or more, of several procedures.

Low heat-content gas is of interest to industry as a fuel gas or even, on occasion, as a raw material from which ammonia, methanol, and other compounds may be synthesized.

See also: Gaseous Fuels.

Gaseous Fuels – Medium Btu Gas

Medium heat-content gas (medium heat-content gas) has a heating value in the range 300 to 550 Btu/ft³, and the composition is much like that of low heat-content gas, except that there is virtually no nitrogen. The primary combustible gases in medium heat-content gas are hydrogen and carbon monoxide. Medium heat-content gas is considerably more versatile than low heat-content gas; like low heat-content gas, medium heat-content gas may be used directly as a fuel to raise steam, or used through a combined power cycle to drive a gas turbine, with the hot exhaust gases employed to raise steam, but medium heat-content gas is especially amenable to synthesize methane (by methanation), higher hydrocarbon derivatives (by Fischer-Tropsch synthesis), methanol, and a variety of synthetic chemicals.

The reactions used to produce medium heat-content gas are the same as those employed for low heat-content gas synthesis, the major difference being the application of a nitrogen barrier (such as the use of pure oxygen) to keep diluent nitrogen out of the system.

In medium heat-content gas, the H₂/CO ratio varies from 2:3 C to 3:1 and the increased heating value correlates with higher methane and hydrogen contents as well as with lower carbon dioxide contents. Furthermore, the very nature of the gasification process used to produce the medium heat-content gas has a marked effect upon the ease of subsequent processing. For example, the CO₂-acceptor product is quite amenable to use for methane production because it has (i) the desired H₂/CO ratio just exceeding 3:1, (ii) an initially high methane content, and (iii) relatively low water and carbon dioxide contents. Other gases may require appreciable shift reaction and removal of large quantities of water and carbon dioxide prior to methanation.

Gases and Naphtha

Methane is the main hydrocarbon component of crude oil gases with lesser amounts of ethane, propane, butane, isobutane, and some C₄⁺ hydrocarbon derivatives. Other gases, such as hydrogen, carbon dioxide, hydrogen sulfide, and carbonyl sulfide, are also present.

Saturated constituents with lesser amounts of mono- and di-aromatics dominate the naphtha fraction. While naphtha covers the boiling range of gasoline, most of the raw crude oil naphtha molecules have low octane number. However, most raw naphtha is processed further and combined with other process naphtha and additives to formulate commercial gasoline.

Within the saturated constituents in crude oil gases and naphtha, every possible paraffin from methane (CH₄) hydrocarbon to n-decane (n-C₁₀H₂₂, normal decane) is present. Depending upon the source, one of these low boiling paraffins may be the most abundant compound in a crude oil reaching several percent. The iso-paraffins begin at C₄ with isobutane as the only isomer of n-butane. The number of isomers grows rapidly with carbon number, and there may be increased difficulty in dealing with multiple isomers during analysis.

In addition to aliphatic molecules, the saturated constituents consist of cycloalkanes (naphthenes) with predominantly five- or six-carbon rings. Methyl derivatives of cyclopentane and cyclohexane, which are commonly found at higher levels than the parent unsubstituted structures, may be present. Fused ring dicycloalkane derivatives such as cis-decahydronaphthalene (cis-decalin) and trans-decahydronaphthalene (trans-decalin) and hexahydro-indan are also common, but bicyclic naphthenes separated by a single bond, such as cyclohexyl cyclohexane, are not.

The numerous aromatic constituents in crude oil naphtha begin with benzene, but its C₁ to C₃ alkylated derivatives are also present. Each of the alkyl benzene homologues through the twenty isomeric C₄ alkyl benzenes have been isolated from crude oil along with various C₅-derivatives. Benzene derivatives having fused cycloparaffin rings (naphthoaromatic derivatives) such as indane and tetralin have been isolated along with a number of their methyl derivatives. Naphthalene is included in this fraction, while the 1- and 2-methyl naphthalenes and higher homologues of fused two ring aromatics appear in the mid-distillate fraction.

Sulfur-containing compounds are the only heteroatom compounds to be found in this fraction. Usually, the total amount of the sulfur in this fraction accounts for less than 1% of the total sulfur in the crude oil. In naphtha from high-sulfur (sour) crude oil, 50 to 70% of the sulfur may be in the form of mercaptans (thiols). Over 40 individual thiols have been identified, including all the isomeric C_1 to C_6 compounds plus some C_7 and C_8 isomers plus thiophenol. In naphtha from low-sulfur (sweet) crude oil, the sulfur is distributed between sulfides (thioethers) and thiophenes. In these cases, the sulfides may be in the form of both linear (alkyl sulfides) and five- or six-ring cyclic (thiacyclane) structures. The sulfur structure distribution tends to follow the distribution hydrocarbon derivatives such as naphthenic oils with a high content of cycloalkane derivatives tend to have a high thiacyclane content. Typical alkyl thiophene derivatives in naphtha have multiple short side chains or exist as naphthothiophene derivatives. Methyl and ethyl disulfides have been confirmed to be present in some crude oils in analyses that minimized their possible formation by oxidative coupling of thiol (mercaptan) derivatives.

Gaseous Hydrocarbons – General Properties

The number of carbon atoms in a member of the paraffin series determines whether the hydrocarbon will exist as a gas, a liquid, or a solid under standard conditions of temperature and pressure (STP' 60°F, 760 mm Hg) (Table G-5). Methane (CH_4) is a gas under all naturally occurring temperature and pressure conditions. Ethane (C_2H_6), propane (C_3H_8), butane (C_4H_{10}), and its isomers are gaseous under standard surface conditions (Table G-5) but may exist in either gaseous or liquid phase under the elevated temperature and pressure conditions found in subsurface reservoirs. On the other hand, members of the paraffin series with between 5 and 17 carbon atoms in their molecular structures (such as pentane, C_5H_{12} , hexane, C_6H_{14} , heptane, C_7H_{16} , octane, C_8H_{18}) are liquid under standard surface conditions and most temperature and pressure conditions encountered in subsurface reservoirs. Members of the paraffin series with more than 17 carbon atoms are solid under most naturally occurring temperatures and pressures and, as a mixture, are often referred to as paraffin wax.

Table G-5 Properties of gaseous (C_1 - C_4) paraffin hydrocarbons.

Gas	Molecular weight	Boiling point 1 atm, °C (OF)	Density at 60°F g/liter	Density Relative to air = 1
Methane	16.043	-161.5 (-258.7)	0.6786	0.5547
Ethylene	28.054	-103.7 (-154.7)	1.1949	0.9768
Ethane	30.068	-88.6 (-127.5)	1.2795	1.046
Propylene	42.081	-47.7 (-53.9)	1.8052	1.4757
Propane	44.097	-42.1 (-43.8)	1.8917	1.5464
1,2- Butadiene	54.088	10.9 (51.6)	2.3451	1.9172
1,3-Butadiene	54.088	-4.4 (24.1)	2.3491	1.9203
1-Butene	56.108	-6.3 (20.7)	2.4442	1.9981
cis-2-Butene	56.108	3.7 (38.7)	2.4543	2.0063
trans-2-Butene	56.108	0.9 (33.6)	2.4543	2.0063
iso-Butene	56.104	-6.9 (19.6)	2.4442	1.9981
n-Butane	58.124	-5.4 (31.1)	2.532	2.0698
iso-Butane	58.124	-11.7 (10.9)	2.5268	2.0656

Gaseous Pollutants

The atmosphere of the Earth is a mixture primarily of the gases nitrogen and oxygen, totaling 99%; nearly 1% water; and small amounts of other gases and substances, some of which are chemically reactive. With the exception of oxygen, nitrogen, water, and the inert gases, all constituents of air may be a source of concern owing either to their potential health effects on humans, animals, and plants, or to their influence on the climate.

The gaseous pollutants are carbon monoxide, nitrogen oxides, volatile organic compounds, and sulfur dioxide. These are reactive gases that in the presence of sunlight contribute to the formation of ground level ozone, smog, and acid rain.

The non-gaseous particulate matter consists of metals and substances such as pollen, dust, and larger particles such as soot from wood fires or diesel fuel ignition.

The greenhouse gases are water vapor, carbon dioxide, methane, nitrous oxide, and a host of engineered chemicals, such as chlorofluorocarbons. These gases regulate the temperature of the Earth, and, when the natural balance of the atmosphere is disturbed particularly by an increase or decrease in the greenhouse gases, the climate of the Earth could be affected.

Most greenhouse gases occur naturally, but concentrations of carbon dioxide and other greenhouse gases in the atmosphere of the Earth have been increasing since the Industrial Revolution with the increased combustion of fossil fuels and increased agricultural operations. The greenhouse effect happens because of certain naturally occurring substances in the atmosphere.

Carbon dioxide is a colorless gas that is a by-product of the combustion of organic matter which comprises less than 0.04% v/v of the atmosphere of the Earth, most of which was put there by volcanic activity early in the life of the Earth. Currently, human activities are pumping huge amounts of carbon dioxide into the atmosphere, resulting in an overall increase in carbon dioxide concentrations. These increased concentrations are considered the primary factor in global warming because carbon dioxide absorbs infrared radiation. Most of the energy that escapes the atmosphere of the Earth is in this form, so extra carbon dioxide means more energy absorption and an overall increase in the temperature of the Earth.

Nitrous oxide (NO_2) is another important greenhouse gas. Although the amounts being released by human activities are not as great as the amounts of carbon dioxide, nitrous oxide absorbs much more energy than carbon dioxide (approximately 270 times as much). For this reason, efforts to curb greenhouse gas emissions have focused on nitrous oxide as well. Methane is a combustible gas, and it is the main component of natural gas and also occurs naturally through the decomposition of organic material and is often encountered in the form of swamp gas. Methane acts much like carbon dioxide in the atmosphere, absorbing infrared energy and keeping heat energy on Earth.

See also: Atmosphere, Pollutant.

Gaseous Pollutants – Control

Any gas that is present in the air in a concentration that causes some deleterious effect is considered a gaseous pollutant. However, there are several substances that, by virtue of their massive rates of emission and harmful effects, are considered the most significant pollutants. Four major primary gaseous air pollutants (so called because they are exited from the exhaust pipe into the atmosphere) include sulfur oxides (SO_x), nitrogen oxides (NO_x), volatile organic compounds (VOCs), and carbon monoxide (CO). Basically, these four pollutants are emitted during fossil fuel combustion both from stationary and mobile sources, but each can be emitted from non-combustion processes as well such as SO_x from smelting furnaces, escape of organic vapors from oil tanks, and NO_x from agricultural operations.

There are several methods that can be used to accomplish control of the emissions of gaseous pollutants. However, the method selected and employed must be chosen according to the types of pollutants. Thus, air pollution control devices are a series of devices that work to prevent a variety of different pollutants (both gaseous and solid) from entering the atmosphere primarily out of industrial smokestacks. These control devices can be separated into two broad categories which are (i) devices that control the amount of particulate matter escaping into the environment

and (ii) devices that control emission of acid gases. It is important to understand that the extraction methods for each specific type of pollutant can differ, and the devices presented below (in alphabetical order rather than by preference or use) have been shown to be effective in the past with the overall levels of emissions for many pollutants dropping with the implementation of these control devices.

Gas Control

More intense chemical methods of separation are generally required to separate polluting gases from the flue gas. However, this extraction is important as many acidic gases in flue gas contribute to acid rain. Below are some of the basic ways that gases can be extracted.

Carbon Capture

Carbon dioxide can theoretically also be captured and stored underground or in forests and oceans to prevent it from entering the atmosphere. Carbon capture and storage refers to the process of capturing this carbon dioxide and storing it below ground, pumping it into geologic layers.

Incineration

Incineration is used to convert emissions of volatile organic compounds into carbon dioxide and water. The incineration generally takes place in a specialized piece of equipment known as an afterburner, which is built to create the conditions necessary for complete combustion (such as sufficient burn time and a high temperature). In addition, the incinerated gas must be mixed to ensure complete combustion.

Scrubbers

Scrubbers are a type of system that is used to remove harmful materials from industrial exhaust gases before they are released into the environment. These pollutants are generally gaseous, and when scrubbers are used to specifically remove sulfur oxides, it is referred to as flue gas desulfurization. There are two main types of scrubbers: (i) wet scrubbers and (ii) dry scrubbers. The main difference is in the type of material used to remove the gases. By removing acidic gases from the exhaust before it is released into the sky, scrubbers help prevent the formation of acid rain.

Particulate Matter

Specific processes are used to remove particulate matter from flue gases. Much of this separation uses physical means of separation and not chemical separation techniques simply because particulate matter is large enough to be «caught» in this manner. Below are some of the basic ways that particulate matter can be extracted.

Cyclone Separators

A cyclone separator is a separation device that uses the principle of inertia to remove particulate matter from flue gases.^[3] In these separators, dirty flue gas enters a chamber containing a vortex, similar to a tornado. Because of the difference in inertia of gas particles and larger particulate matter, the gas particles move up the cylinder while larger particles hit the inside wall and drop down. This separates the particulate matter from the flue gas, leaving cleaned gas stream.

Electrostatic Precipitators

An electrostatic precipitator is a type of filter that uses static electricity to remove soot and ash from gas streams before the gas enters the atmosphere. Unburned particles of carbon in the gas stream are removed from the stream by using static electricity in the precipitators.

Fabric Filters

Fabric filters can be used to remove dust from flue gases. In some gases, they can also remove acidic gases if they utilize basic compounds. This method simply uses a fabric – generally, felt is used as a woven cloth would allow dust to make its way through which is placed so that flue gasses must pass through it before exiting into the atmosphere. When the gas passes through, dust particles are trapped in the cloth.

See also: Gas Cleaning, Acid Rain.

Gasification

Gasification is a chemical or thermal process used to convert carbonaceous material (such as coal, crude oil, and biomass) into gaseous components such as carbon monoxide and hydrogen.

Gasification, among the several thermochemical conversion processes, possesses great potential in the advanced utilization of biomass and wastes as a source for energy and material.

In the gasification process, biomass and solid waste are transformed into gas, which can be burned directly as fuel or used as a raw material for synthesis gas or hydrogen production. Considerable environmental importance rests upon the development of highly efficient power cycles and on the production of liquid biofuels and hydrogen from these renewable energy sources. Even though gasification technologies have recently been successfully demonstrated, they continue to be expensive relative to energy production based on fossil fuels. Strong drivers to develop and commercialize biomass and waste gasification exist, however, in face of the urgent need to increase the rates of biomass use and waste recycling and to improve the efficiency of their use in electricity production.

The primary objective of biomass gasification is to convert as much of the feed material as possible to a gaseous product. A secondary objective might be to increase the H_2/CO ratio of the gas over that obtained in pyrolysis so as to facilitate downstream upgrading. This latter objective can be effectively achieved using a subsequent gas shift step. Apart from upgrading to synthetic natural gas, liquid products can be produced by the Fischer-Tropsch synthesis.

The feedstock entering a gasifier is first dried by rising hot gases. Further heating results in the devolatilization and pyrolysis reactions discussed in the previous section. In the next stage, temperatures are sufficiently high for the gasification reactions to proceed.

The raw gas produced on gasification of a carbonaceous feedstock has a low-to-medium-calorific value, depending on whether air or oxygen is used as the oxidant in directly heated gasifiers. The product from indirectly heated gasifiers, in which an inert material is typically used to transfer the heat from an external source, is generally a medium-heat content gas. The energy in these gases could theoretically be utilized directly, for example, by generation of electricity, either by raising steam in a boiler or by combustion in a gas turbine.

The gases produced on gasification do not satisfy the clean fuel criteria, and so further processing is necessary. Removal of pollutant gases such as ammonia and hydrogen sulfide, and inert gases such as carbon dioxide, is an obvious requirement. Gas purification processes do not involve reactions of the active gas components.

Gasification with air results in a low-heat content gas that can be used for combined cycle electricity generation. Increased efficiencies attained with combined cycle systems gasifying conventional fossil fuels arise in part from the more effective pollution control techniques that may be used. In the case of biomass, sulfur concentrations are low, so its direct combustion does not require an attendant energy-consuming flue gas desulfurization step. Other factors including nitrogen oxide emissions, the inherent greater efficiency of gas turbines, and the limited scale of operations, will determine whether or not combined cycle generation with biomass will be more viable than conventional steam-electric generation.

If heat or steam is the desired product, then again air gasification appears to offer little advantage over direct combustion as far as pollution control is concerned. It is possible that air gasification may prove useful as a means of providing a substitute fuel for existing gas-fired boilers.

A gasifier supplying fuel to an adjacent boiler is termed a close-coupled system, which has the potential for a higher efficiency than is achievable with direct combustion of most fuels such as biomass. High-moisture feedstocks have lower flame temperatures, which can result in particulate and tar emissions and lower boiler efficiencies.

Once gasified, however, the moisture is in the vapor state and improved combustion efficiencies can be achieved. Nevertheless, high-moisture-content fuel gases may have undesirable characteristics for existing equipment, so some degree of predrying may in any case be required.

There is considerable interest in using catalysts to enhance the performance of both pyrolysis and gasification systems. As biomass contains low concentrations of sulfur and other catalyst poisons, the rapid deactivation of some catalysts that occurs with fossil fuels is not a problem. Alkali metal carbonates have been shown to increase the rate and extent of low temperature wood gasification. The use of these catalysts is discussed in Section 4.4 in connection with coal gasification. As mentioned, biomass materials have a high-volatile-matter content, and the small amount of char remaining on rapid pyrolysis is highly reactive relative to coal chars. The role of a catalyst would therefore seem to be more one of controlling gas phase reactions rather than promoting gas yields.

Gasification Chemistry

When fuel is fed to a gasifier, water and volatile matter are released fast and a char residue is left to react further. The char gasification is what mainly controls the conversion achieved in the process. From solid carbon, product gas is formed according to the following main reactions:

In addition to the reactions of solid carbon, the most important reaction is the water-gas shift reaction, which takes place in the gas phase:

The product gas generally contains large amounts of hydrogen and carbon monoxide and a small amount of methane, as well as carbon dioxide and steam, and in air gasification nitrogen. In addition, a significant amount of other organic components in the gas, known as tar, is formed.

See also: Gasification; Gasification (Volume 3: Coal).

Gasification of Biomass

Gasification of biomass is a process in which solid biomass fuels are broken down by the use of heat in an oxygen-starved environment, to produce a combustible gas. Biomass fuels that can be gasified include wood, charcoal, rice husks, coconut shells, and a variety of other dry biomass materials. A biomass gasification system consists primarily of a reactor into which fuel is fed along with a limited (less than stoichiometric or that required for complete combustion) supply of air. Heat for gasification is generated through partial combustion of the feed material. The resulting chemical breakdown of the fuel and internal reactions result in a combustible gas usually called producer gas.

The primary objective of biomass gasification is to convert as much of the feed material as possible to a gaseous product. A secondary objective might be to increase the H_2/CO ratio of the gas over that obtained in pyrolysis so as to facilitate downstream upgrading. This latter objective can be effectively achieved using a subsequent gas shift step. Apart from upgrading to synthetic natural gas, liquid products can be produced by the Fischer-Tropsch synthesis.

In the process, the feedstock (biomass which may also be co-gasified with solid waste) is transformed into gas, which can be burned directly as fuel or used as a raw material for synthesis gas or hydrogen production. Considerable environmental importance rests upon the development of highly efficient power cycles and on the production of liquid biofuels and hydrogen from these renewable energy sources. Even though gasification technologies have recently been successfully demonstrated, they continue to be expensive relative to energy production based on fossil fuels. Strong drivers to develop and commercialize biomass and waste gasification exist, however, in face of the urgent need to increase the rates of biomass use and waste recycling and to improve the efficiency of their use in electricity production.

The feedstock entering a gasifier is first dried by rising hot gases. Further heating results in devolatilization and pyrolysis reactions. In the next stage, temperatures are sufficiently high for the gasification reactions to proceed.

The raw gas produced on gasification of a carbonaceous feedstock has a low-to-medium calorific value, depending on whether air or oxygen is used as the oxidant in directly heated gasifiers. The product from indirectly heated gasifiers, in which an inert material is typically used to transfer the heat from an external source, is generally a medium-heat content gas. The energy in these gases could theoretically be utilized directly, for example by generation of

electricity, either by raising steam in a boiler or by combustion in a gas turbine. However, the gases produced on gasification do not satisfy the clean fuel criteria, and so further processing is necessary. Removal of pollutant gases such as ammonia and hydrogen sulfide, and inert gases such as carbon dioxide, is an obvious requirement. Gas purification processes do not involve reactions of the active gas components.

Gasification with air results in a low-heat content gas that can be used for combined cycle electricity generation. Increased efficiencies attained with combined cycle systems gasifying conventional fossil fuels arise in part from the more effective pollution control techniques that may be used. In the case of biomass, sulfur concentrations are low, so its direct combustion does not require an attendant energy-consuming flue gas desulfurization step. Other factors including nitrogen oxide emissions, the inherent greater efficiency of gas turbines, and the limited scale of operations, will determine whether or not combined cycle generation with biomass will be more viable than conventional steam-electric generation.

If heat or steam is the desired product, then again air gasification appears to offer little advantage over direct combustion as far as pollution control is concerned. It is possible that air gasification may prove useful as a means of providing a substitute fuel for existing gas-fired boilers.

A gasifier supplying fuel to an adjacent boiler is termed a *close-coupled system*, which has the potential for a higher efficiency than is achievable with direct combustion of most fuels such as biomass. High-moisture feedstocks have lower flame temperatures, which can result in particulate and tar emissions and lower boiler efficiencies. Once gasified, however, the moisture is in the vapor state and improved combustion efficiencies can be achieved. Nevertheless, high-moisture-content fuel gases may have undesirable characteristics for existing equipment, so some degree of pre-drying may in any case be required.

There is considerable interest in using catalysts to enhance the performance of both pyrolysis and gasification systems. As biomass contains low concentrations of sulfur and other catalyst poisons, the rapid deactivation of some catalysts that occurs with fossil fuels is not a problem. Alkali metal carbonates have been shown to increase the rate and extent of low-temperature wood gasification.

Biomass materials have a high-volatile-matter content, and the small amount of char remaining on rapid pyrolysis is highly reactive relative to coal chars. The role of a catalyst would therefore seem to be more one of controlling gas phase reactions rather than promoting gas yields.

A gasification system consists of four main stages which are (i) feeding, (ii) gasifier, (iii) gas cleaning, and (iv) utilization of combustible gas.

Feeding is important, and especially the feeding of pressurized systems is seen as problematic (such as mechanical issues and tight gas issues). Some genius level engineering solutions are required in this area. Low-pressure gasifiers can adopt a lot of the technology developed for combustion of biomass.

Biomass gasification systems offer several advantages over direct combustion systems. Gasification reduces corrosion compared to direct combustion because of the lower temperatures in the gases. Gasifiers can convert the energy content of a feedstock to hot combustible gases at 85% to 90% thermal efficiency. In addition, the fuel throughput per unit area is greater for gasification than combustion, which means that smaller gasification units can process the same amount of fuel as larger combustion units. In addition, approximately 80% of the usable energy is in the form of chemical energy in the gas. A final advantage is that, if desired, the materials that cause slagging can be removed at relatively high temperatures through a gas clean-up process. These last two statements imply that the gas can be cleaned up and used at higher temperatures without significant loss of sensible heat, although the costs to do so can be considerable.

Characterization of biomass for gasification and other thermochemical processes is often based solely on determination of the general fuel characteristics (e.g., proximate and ultimate analysis, heating values, ash fusion temperatures, etc.), the chemical composition and physical properties relevant for gasification. Also included are particle shape, particle size and size distribution, flow properties, and bulk density.

Waste-based fuels are characterized in the same way as the conventional fuels. Mixed paper waste is an attractive energy source since it is relatively homogeneous and mostly free of putrescible matter, metals, and other non-combustible constituents. Minimal processing is required to convert it to fuel for gasification, and, when processed into densified fuel, the heating value is close to that of wood.

Each type of biomass has its own specific properties which determine its performance as a fuel in gasification plants. The most important feedstock properties relating to gasification are (i) moisture content, (ii) mineral matter

content, (iii) elemental composition, (iv) bulk density and morphology, and (5) volatile matter content. For thermal conversion processes like gasification, preference is given to relative dry biomass feedstocks because a higher-quality gas is produced, i.e., higher heating value, higher efficiency, and lower tar levels.

The amount of ash produced by different type of feedstocks differs widely (0.1% for wood up to 15% w/w for some agricultural products) and influences the design of the reactor, particularly the ash removal system. The chemical composition of the ash is also important because it affects the melting behavior of the ash. Ash melting can cause slagging and channel formation in the reactor. Slag can ultimately block the entire reactor.

The elemental composition of the fuel is important with regard to the heating value of the gas and to the emission levels. The production of nitrogen and sulfur compounds is generally small in biomass gasification because of the low nitrogen and sulfur content in biomass.

Bulk density refers to the weight of material per unit of volume and differs widely between different types of biomass. Together with the heating value, the bulk density of the feedstock determines the energy density of the gasifier feedstock, i.e., the potential energy available per unit volume of the feedstock. Biomass of low bulk density is expensive to handle, transport, and store. Apart from handling and storing behavior, the bulk density is important for the performance of the biomass as a fuel inside the reactor: a high voidage tends to result in channeling, bridging, incomplete conversion, and a decrease in the capacity of the gasifier. The bulk density varies widely (100-1,000 kg/m³) between different biomass feedstocks, as a result of the manner in which the biomass becomes available (chips, loose, baled, etc.).

The amount of volatile products has a major impact on the tar production levels in gasifiers. Depending on the gasifier design, the volatiles leave the reactor at low temperatures (updraft gasifiers) or pass through a hot incandescent oxidation zone (downdraft gasifiers) where they are thermally cracked. For biomass materials, the volatile matter content varies between 50 and 80%.

Gasification of Biomass – Feedstock Preparation

Different biomass characteristics results in the necessity to pretreat/process different types of biomass feedstocks when they are going to be used as a gasifier fuel. The need for a suitable feed preparation system is well known but unfortunately poorly understood.

Feedstock preparation is required for almost all types of biomass materials because of a large variety in physical, chemical, and morphological characteristics. The degree to which any specific pretreatment is desirable will depend on the details of the gasifier plant, such as capacity and type of reactor (downdraft gasifiers are more strict to uniform fuel specifications than updraft gasifiers) (Table G-6).

Any listed fuel characteristics can be influenced by pretreatment process – for example, mineral additives can influence the ash melting behavior. However, the most important pretreatment technologies are drying, sizing, and densification. Other pretreatment technologies like screening and sifting are only of importance to specific materials like heavy contaminated demolition materials such as sand, paper, plastic, non-ferrous metals, ferrous metals, and demolition wood.

Table G-6 General guidelines for fuel requirements for different gasifier types.

Gasifier type:	Downdraft	Updraft	Cross draft
Size, mm	20-100	5-100	40-80
Moisture, % w/w	<20	<50	<7
Bulk density	>500	>400	>400
Ash yield, % w/w	<5	<15	<6
Ash melting point °C	>1,250	>1,250	>1,250

Sizing of the feedstock may be necessary as different sizes are specified for different types of gasifiers. For small-scale fixed-bed gasifiers, cutting and/or sawing of wood blocks is the preferred form of fuel preparation. Chipped

wood is preferred for larger-scale applications. The size range of chips can be chosen by screening such that the fuel is acceptable for a specific gasifier type. For medium- and large-scale fixed-bed gasifiers, wood chips from forestry or wood processing industries are produced by crushers, hammermills, shredders, and/or mobile chippers (particularly for thinnings from landscape conservation activities). Most of these sizing apparatus are provided with a screen. Depending on the feedstock morphology and characteristics (hardness), the throughput or capacity of these techniques varies widely.

Drying of the fuel is advisable if fresh wet materials (moisture content 50-60% on wet basis) are to be gasified. As outlined previously under § 1.2.3, lowering the moisture content of the feedstock is associated with a better performance of the gasifier. Utilizing the exhaust gases from an internal combustion engine is a very efficient way to do so. The sensible heat in engine exhaust is sufficient to dry biomass from 70% down to 10%. Rotary kilns are the most applied dryers. The energy costs of drying are high, but these can be outweighed by the lower downstream gas cleaning requirements for dried feed.

Briquetting or pelletization is an important technique to densify biomass materials for increasing the particle size and bulk density. The reasons for densification are (i) the densified biomass is less expensive to transport, (ii) the densified products are easier to store and handle, and (iii) densification enables certain biomass feedstocks to be gasified in a specific gasifier.

The sequence of pretreatment technologies depends on the type and characteristics of the biomass material and the requirements of the gasifier fuel. The following aspects are important in the biomass pretreatment sequence which is (i) the larger materials such as window-frames need to be sized in two or more steps, (ii) the wet materials like waste from public gardens requires more drying energy compared to dry materials like demolition wood, (iii) artificial drying of larger materials requires more time compared to fine materials like sawdust, (iv) wet materials like thinnings, waste from public gardens, and green waste (vegetable, fruit, and garden) have a generally small particle size, (v) screening of wet materials is a less efficient process compared to screening of dry materials, and (vi) hammermills can only be applied for relatively dry materials; for sizing of wet materials, chippers provided with a knife must be applied.

Gasification Reactors

Three principal reactor types are employed in gasifier design: the moving packed bed, the fluidized bed, and the entrained flow reactor. A fourth type, the molten media reactor (or molten salt reactor), could be grouped together with the entrained flow reactor, but is sufficiently distinctive in its operation that it should be treated separately.

Fixed bed gasifiers are suitable for small-scale processes, i.e., less than 10 MW. Feedstock flows by gravity, while the gas flow can be either updraft or downdraft. Ideally, the feedstock should be piece-like and fairly homogeneous to flow smoothly in the reactor. In practice, however, it contains fines and fibrous material, which cause problems in the fuel flow leading to operational problems. The flow problems can be avoided by applying a new type of technology (novel fixed-bed gasifier), in which the flow is forced.

Fluidized bed reactors could solve the problems related to non-homogeneity of the feedstock, but they are too expensive in a small scale. In fluidized bed technology, the feedstock must be crushed to millimeter size before it is gasified in either bubbling or circulating mode. These gasifiers are suitable for scales up to hundreds of megawatts. Recently, fluidized bed technology was applied for wastes where the product gas is combusted in a pulverized coal-fired boiler. The same method has been used to recover aluminum from the reject produced in liquid packaging board (LPB) recycling. The circulating fluidized bed has been demonstrated to be particularly suited for fuels containing high contents of alkali metals, where ash sintering problems can be avoided by using limestone and special arrangements with the feeds.

In the third type of gasifier, the entrained flow gasifier, pulverized fuel is gasified at high temperature. This is regarded as one of the optional processes for liquid fuel manufacture from biomass and wastes. High pressure gasification based on the entrained flow process can be applied to improve the energy recovery from black liquor.

The reactor type strongly influences the temperature distribution, and in this way the gas and residue products. The reaction temperature varies from approximately 815 to 1,925°C (1,500 to 3,500°F), with each type of gasifier covering

a specific range. The exception to this is the molten media gasifier whose temperature and, to some extent, characteristics of operation are determined by the melt employed.

At high temperatures, a synthesis gas is produced and at low temperatures, methane formation is favored. As the overhead product is affected, so is the residue. Gasifiers in which the temperature is low enough that the ash does not melt are sometimes referred to as dry bottom gasifiers. High temperature gasifiers in which molten ash (slag) is formed are called slagging gasifiers. The slagging temperature is dependent on the ash composition, but for most coals lies roughly in the range 1,200 to 1,800°C (2,190 to 3,270°F).

In the terminology of gasifier technology, the term fixed bed gasifier refers to a gasifier in which a packed bed of fuel is supported by a grate or by other means and maintained at a constant depth above the support. The fuel moves downward under the action of gravity from the top of the gasifier, through the gasification and combustion zones, and the residue is discharged at the bottom. Within the reactor classes, this is a moving packed bed or a moving bed reactor.

Moving bed gasifiers operate with countercurrent flow, use either steam and oxygen or steam and air, and the residue may be slag or dry ash plus any unconverted carbon. Undried feedstock particles that range in size between 3 and 50 mm are fed into the top of the gasifier, with the size range dependent on the particular process. The particle sizes must be sufficiently large (>3 mm) in order that they not be carried out overhead by the exiting product gases. Smaller particles, termed fines, must be removed from the feedstock, not only because of the carry-over problem, but also because they tend to clog the bed and offer a high resistance to the upward flowing gases.

The feedstock passes downward through the upward flowing gases, first being heated, then devolatilized, and then still lower down gasified. The bottom of the coal bed is the combustion zone, with the residue of the combustion cooled by the steam/oxygen or steam/air mixture entering from the bottom before it is discharged. The downward movement of the bed is relatively slow, with average linear velocities on the order of 0.5 m/h in atmospheric steam/air gasifiers and 5 m/h in high pressure steam/oxygen gasifiers. Feedstock residence times are correspondingly shorter with the higher velocity beds, and are typically on the order of 0.5 to 1 hour for the high pressure steam/oxygen gasifiers and some ten times longer for atmospheric steam/air gasifiers.

Temperatures in the combustion zone are mainly a function of the relative level of the oxidant. In atmospheric steam/air gasifiers, temperatures do not exceed the ash melting point. Steam/oxygen gasifiers may, however, be either dry ash or slagging depending on the amount of steam blown into the gasifier in relation to the amount of oxygen.

In dry ash gasifiers, a large quantity of steam is blown in, which holds down the temperature by virtue of its high heat capacity, and because the steam-carbon gasification reaction is endothermic. The excess steam does not participate in the reaction and is recovered from the product gases as dirty water. The maintenance of lower combustion temperatures by excess steam addition is critical for gasifiers designed for dry ash operation, since if the ash melts, it then cannot be handled on a supporting grate.

The excess steam requirement can be overcome by operating at high temperatures in a slagging mode. By deliberately operating at high temperatures, excess steam is no longer required to hold down the temperature. A second, but important, effect is that the rate of the carbon-steam reaction is enhanced at elevated temperature resulting in improved steam utilization and little undecomposed steam in the product gases. The absence of undecomposed steam coupled with lower carbon dioxide contents, because of the higher combustion temperatures, minimizes the amount of diluent gases that pass through the gasifier. The result is a higher product gas output, all else being equal. The penalty for this mode of operation is that handling of molten slag is required. The Lurgi gasifier, which was first run commercially in 1936, has been developed to operate in both the dry ash and slagging modes.

Combustion temperatures are also dependent on the reactivity of the feedstock. Less reactive feedstocks attain higher maximum combustion temperatures and require a higher steam/oxygen ratio to hold the temperature below a given ash melting point.

An advantage of the moving bed gasifier is that the countercurrent direct contact heat exchange that takes place within the gasifier results in relatively high overall conversion efficiency with a minimum of heat loss.

Entrained flow gasifiers all use feedstock pulverized to a size on the order of 75 μ m. Oxygen or air together with steam generally is used to entrain the feedstock, which is injected through nozzles into the gasifier burner. Hot product gas, or in the case of hydrogasification hot hydrogen, may also be used to entrain the feedstock and at the same time gasify it. In the Texaco gasifier, the solids are carried in a water slurry. However, in a preheater, the water is turned into steam, and it is the steam plus feedstock that is blown into the reactor.

Entrained flow reactors have the advantage of having high throughput rates, especially with higher pressure operation. But because they are co-current flow systems, they are not the most efficient thermally. Moreover, the high off gas temperature, that is the temperature of the gas coming off the top of a gasifier, introduces additional losses through the requirement for irreversible quenching. The high temperature environment also imposes severe operating conditions, including the problem of mineral slag handling and removal.

Fluidized bed gasifiers are fed with pulverized or crushed feedstock that is lifted in the gasifier by feed and product gases. In single stage, directly heated gasifiers, a steamy oxygen or steam/air mixture is injected near the bottom of the reactor, either co-current or countercurrently to the flow of the feedstock. The rising gases react with the feedstock and at the same time maintain it in a fluidized state. As feedstock gasification occurs, the larger size mineral particles, which are approximately twice as dense as the carbonaceous material, fall down through the fluidized bed together with larger char particles. The smaller and low-density particles of unconverted carbon, char, and ash are carried upward with the product gases.

Advantages of fluidized beds include good mixing of the solids and a uniform temperature bed, with rapid temperature equilibration between the solids and gases. As a consequence, fluidized bed gasifiers have the advantage that there is efficient heat transfer from the exothermic to the endothermic regions, and therefore, the gasification reactions reach equilibrium quickly, resulting in relatively high throughputs. A disadvantage of most fluidized bed gasifiers is the potential for carry-over of solids in the product gas, and a means of removing this carry-over has to be incorporated.

In molten media gasifiers, the feedstock is dispersed into a molten carrier, which generally takes part in the gasification and acts as a heat source. The feedstock particles are, for the most part, entrained in the slag, which promotes the gasification reactions and certain constituents, such as iron oxide, act as oxygen-transfer agents through oxidation and reduction reactions.

The temperature in molten media gasifiers depends upon the melt, but as a group, they have the advantage that they can accept all types of feedstocks and provide an efficient heat sink for the promotion of gasification reactions. However, a limitation is that the processes must handle the molten media and, for example, in the case of molten salt, regenerate and recycle an extremely corrosive material.

Gasifiers

A gasifier is a device for converting solid fuel into gaseous fuel; in biomass systems, the process is referred to as pyrolytic distillation. Some few gasifiers have already been in operation for several decades, and a number of gasification processes are under industrial development at pilot and demonstration scale.

A range of feedstock is available for gasification and varies from clean biomass to waste fuels containing different amounts of ash, alkaline, and emission precursors like nitrogen chlorine, and sulfur. A wide range of applications has been developed and demonstrated for (co)-firing in boilers/furnaces, gas engines, and combined cycles. For some applications, it is important to increase gas-heating value. Low heating value gas has some impact on power generation, which has to be considered such as power de-rating and flame stability.

See also: Gasification – Reactors

Gasifiers – Bubbling Fluidized Bed Gasifier

The bubbling fluidized bed gasifier is one of the most popular designs for biomass gasification. The gasifier consists of a vessel in which the gasifying agent is introduced upward at a velocity fast enough to agitate the bed material which sits at the bottom part of the gasifier and to maintain the required temperature. Biomass is fed from the side into the hot bed, where devolatilization occurs. Char particles and volatiles (tar precursors) are gasified and cracked by contact with the hot fluidized bed. Additional gasifying agent can be supplied in a second zone located above the bed with the aim of converting entrained unconverted volatiles and char particles into fuel gas. A final flue gas

with low to medium tar content is produced. Ash is separated from the synthesis gas in gas-solid separation units downstream.

The gasifying agent can be supplied in two different zones. The first zone is within the fluidized bed in order to maintain the required temperature. The second zone is located above the bed, and it aims to convert entrained unconverted volatiles and char particles into fuel gas.

See also: Gasification.

Gasifiers – Circulating Fluidized Bed Gasifier

The circulating fluidized bed (CFB) gasifier is a type of fluidized bed gasifier that utilizes a recirculating loop for even greater efficiency of gasification while achieving lower production (and emission) of pollutants. The gasifier is a natural extension of the bubbling fluidized bed gasifier, with cyclones or other separators employed to capture and recycle solids in order to extend the solids' residence time. The riser of a circulating fluidized bed gasifier operates in either the turbulent or fast fluidization flow regime.

Circulating fluidized beds operate in the regime of fast fluidization, while the bubbling fluidized beds operate in the regime of bubbling fluidization. This difference has a number of consequences for the gasification process, depending on which type of the fluidized bed reactor. In a circulating fluidized bed operating in the fast fluidization flow regime, particles tend to migrate outwards toward the wall, driven by fluid-particle interactions and boundary effects, and descend along the wall, while dilute upon is maintained in the inner core. As a result of the higher concentration of particles in the wall region, there is a reducing region there, with augmented methane, hydrogen, and carbon monoxide concentrations

See also: Gasification.

Gasifiers – Cross Draft Gasifier

The cross draft gasifier is one of the simplest types of gasifier. The reactor for this gasification is much like the updraft gasifier in that the fuel will enter from the top and the thermochemical reaction will occur progressively as this fuel descends into the reactor. The crucial difference is that the air will be entering the gasifier from the side of the reactor, rather than from the top or the bottom. The start-up time for this reactor is relatively short, and high temperatures can be attained using this type of gasification. Cross draft gasification isn't seen very often in commercial processes mainly because other gasification methods offer more flexibility with respect to fuel types; this type of gasification doesn't handle fuel that has a high tar content, and bridging can be a consequence of the particle size of the fuel.

Although cross draft gasifiers have certain advantages over updraft and downdraft gasifiers, they are not ideal. The disadvantages such as high exit gas temperature, poor CO₂ reduction, and high gas velocity are the consequences of the design. Unlike downdraft and updraft gasifiers, the ash bin, fire, and reduction zones in cross draft gasifiers are separate. These design characteristics limit what kind of fuel can be used, restricting it to only low ash fuels such as wood, charcoal, and coke. The load following ability of cross draft gasifier is quite good due to concentrated zones which operate at temperatures up to 1,200°C. Startup time (5-10 minutes) is much faster than that of downdraft and updraft units. The relatively higher temperature in cross draft gas producer has an obvious effect on exit gas composition such as high carbon monoxide and low hydrogen and methane content when dry fuel such as charcoal is used. Cross draft gasifier operates well on dry air blast and dry fuel.

See also: Gasification.

Gasifiers – Downdraft Gasifier

In an updraft gasifier (also referred to as the co-current gasifier), there is a problem of tar entrainment in the product gas leaving stream. A solution is to have primary gasification air introduced at or above the oxidation zone in the gasifier. The produced gas is taken out from the bottom; hence, fuel and gas move in the same direction. On the way down, the acid

and tarry distillation products from the fuel must pass through a glowing bed of charcoal and therefore are converted into permanent gases hydrogen, carbon dioxide, carbon monoxide, and methane. Depending on the temperature of the hot zone and the residence time of the tarry vapors, more or less a complete breakdown of the tars is achieved.

The main advantage of downdraft gasifier lies in the possibility of producing tar-free gas for engine operation. However, in practice, very rarely tar-free gas is produced but the percentage of tar leaving in product stream is considerably lower than leaving through the updraft gasifier.

The main disadvantage is that downdraft gasifier cannot be operated with a range of different feedstocks. Low density feedstock gives rise to flow problems and excessive pressure drop. High ash content coal also gives more problem with this kind of gasifier than updraft gasifier. Another disadvantage is the lower efficiency, since there is no provision internal exchange compare to updraft gasifier. The product stream also has low calorific value.

See also: Gasification.

Gasifiers – Entrained Bed Gasifier

In an entrained bed gasifier, the feedstock and oxygen enter in co-current flow. The feedstock is grounded to a size of 100 μm or less to promote mass transfer and allow transport of solids using gas flow. The key characteristics of entrained flow gasification are high and uniform temperatures (usually more than 1,000°C, >1,830°F) and the short residence time of the fuel within the gasifier. Because of the high temperatures, high conversion is possible. The high temperature operation requires high oxygen demand for these types of processes.

In the process, ash is withdrawn in the molten form. Solids fed into the gasifier must be very finely ground and homogeneous, which in turn means that entrained flow gasifiers are not suitable for feedstocks such as biomass or wastes, which cannot be readily pulverized.

See also: Gasification.

Gasifiers – Fluidized Bed Gasifier

The operation of both updraft and downward draft gasifiers is influenced by the morphological, physical, and chemical properties of the fuel. Problems commonly encountered are (i) lack of bunker flow, (ii) slagging, and (iii) extreme pressure drop over the gasifier.

In the fluidized bed gasifier, air is blown through a bed of solid particles at a sufficient velocity to keep these in a state of suspension. The bed is originally externally heated, and the feedstock is introduced as soon as a sufficiently high temperature is reached. The fuel particles are introduced at the bottom of the reactor, very quickly mixed with the bed material and almost instantaneously heated up to the bed temperature. As a result of this treatment, the fuel is pyrolyzed rapidly which results in a component mix with a relatively large amount of gaseous materials. Further gasification and tar-conversion reactions occur in the gas phase. Ash particles are also carried over the top of the reactor and have to be removed from the gas stream if the gas is used in engine applications. To remove ash particles, cyclone and candle filter are used.

The major advantage of fluidized bed is processing of feedstock. This type of gasifier are mostly used for high ash coal and biomass. Since the temperature is below the ash softening temperature, handling of ash is relatively simple. A drawback of the fluidized bed gasifiers is the high tar content in the produced synthesis gas and incomplete carbon conversion.

See also: Gasification.

Gasifiers – Moving Bed Gasifier

In the moving bed gasifier, the feedstock enters at top and moves downward through gravity and is gasified by the upcoming countercurrent air/oxygen and steam mixture. The hot synthesis gas from gasification zone is used to pre-heat and pyrolyze the downward flowing feedstock. With this process, the oxygen consumption is low, but pyrolysis

products are present in the product synthesis gas. This gasifier can operate on coarse (lump) feedstock, and the outlet temperature of syn gas is generally low.

See also: Gasification.

Gasifiers – Updraft Gasifier

The updraft gasifier (also referred to as the co-current gasifier) is the oldest and simplest of all gasifier types. The air comes in at the bottom and produced syn gas leaves from the top of the gasifier. Near the grate at the bottom, combustion reaction occurs; above that, reduction reaction occurs. In the upper part of the gasifier, heating and pyrolysis of the feedstock occur as a result of heat transfer by forced convection and radiation from the lower zones. Tars and volatile produced during the reaction will leave along with the syn gas at the top of the gasifier, which will be later separated by use of cyclone and candle filter.

The major advantages of this type of gasifier are (i) simplicity, (ii) high charcoal burn out, and (iii) internal heat exchange leading to low temperature of exit gas and high equipment efficiency. This gasifier can work with several kinds of feedstock ranging from coal to biomass.

The major drawbacks of the gasifier result from the possibility of channeling in the equipment, which can lead to oxygen break-through and dangerous, explosive situations and the necessity to install an automatic moving grate.

See also: Gasification.

Gas Laws

Many gas streams produced as alternative fuels are natural gas, and the petroleum-derived gases before separation, are typically a non-ideal gas and follow the gas law:

$$PV = nZRT$$

P is the pressure, V is the volume, T is the absolute temperature (degree Kelvin), Z is the compressibility factor, n is the number of kilo-moles of the gas, and R is the gas constant. For example, if all other factors remained constant, when the volume of a certain mass of gas is reduced by 50%, the pressure would double and so on. As a gas, it would expand to fill any volume it is in. However, the compressibility, Z, is the factor that differentiates natural gas from an ideal gas. For methane, Z is 1 at 1 bar but decreases to 0.85 at 100 bar, both at 25°C, that is, it compresses to a smaller volume than the proportional relationship.

Boyle's Law: The Pressure-Volume Law

Boyle's law or the *pressure-volume law* states that the volume of a given amount of gas held at constant temperature varies inversely with the applied pressure when the temperature and mass are constant.

$$V \propto \frac{1}{P}$$

Another way to describe it is saying that their products are constant.

$$PV = C$$

When pressure increases, the volume decreases. When volume increases, the pressure decreases. From the equation above, this can be derived:

$$P_1 V_1 = P_2 V_2 = P_3 V_3 \text{ etc.}$$

This equation states that the product of the initial volume and pressure are equal to the product of the volume and pressure after a change in one of them under constant temperature.

Charles' Law: The Temperature-Volume Law

This law states that the volume of a given amount of gas held at constant pressure is directly proportional to the Kelvin temperature.

$$V \propto T$$

A constant can be inserted:

$$V/T = C$$

As the volume increases, the temperature also increases, and vice-versa. Also same as before, initial and final volumes and temperatures under constant pressure can be calculated.

$$V_1/T_1 = V_2/T_2 = V_3/T_3 \text{ etc.}$$

Gay-Lussac's Law: The Pressure Temperature Law

This law states that the pressure of a given amount of gas held at constant volume is directly proportional to the Kelvin temperature.

$$P \propto T$$

A constant can be inserted:

$$P/T = C$$

As the pressure increases, the temperature also increases, and vice-versa. Also, initial and final volumes and temperatures under constant pressure can be calculated:

$$P_1/T_1 = P_2/T_2 = P_3/T_3 \text{ etc.}$$

Avogadro's Law: The Volume Amount Law

This law gives the relationship between volume and amount when pressure and temperature are held constant. Remember amount is measured in moles. Also, since volume is one of the variables, that means the container holding the gas is flexible in some way and can expand or contract. If the amount of gas in a container is increased, the volume increases. If the amount of gas in a container is decreased, the volume decreases:

$$V \propto n$$

A constant can be inserted:

$$V/n = C$$

This means that the volume-amount fraction will always be the same value if the pressure and temperature remain constant.

$$V_1/n_1 = V_2/n_2 = V_3/n_3 \text{ etc.}$$

The Combined Gas Law

In the Combined Gas Law, the relevant data from above can be combined into one proportion:

$$V \propto \frac{T}{P}$$

The volume of a given amount of gas is proportional to the ratio of its Kelvin temperature and its pressure. A constant can be inserted:

$$PV/T = C$$

As the pressure increases, the temperature also increases, and vice-versa. Also same as before, initial and final volumes and temperatures under constant pressure can be calculated:

$$P_1 V_1 / T_1 = P_2 V_2 / T_2 = P_3 V_3 / T_3 \text{ etc.}$$

Ideal Gas Law

The previous laws all assume that the gas being measured is an *ideal gas*, a gas that obeys them all exactly. But, over a wide range of temperature, pressure, and volume, real gases deviate slightly from ideal. Since, according to Avogadro, the same volumes of gas contain the same number of moles, chemists could now determine the formulas of gaseous elements and their formula masses. The ideal gas law is:

$$PV = nRT$$

where n is the number of moles and R is the *universal gas constant* and is equal to approximately 0.0821 L-atm/mole-K.

Other Forms of the Gas Law

If the definition of the mole is included in the equation, the result is:

$$PV = gRT/FW$$

or

$$FW = gRT/PV$$

This equation provides a convenient way of determining the formula weight of a gas if the mass, temperature, volume, and pressure of the gas are known (or can be determined).

Dalton's Law of Partial Pressures

Dalton's Law of Partial Pressures states that the total pressure of a mixture of non-reacting gases is the sum of their individual partial pressures.

$$P_{\text{total}} = P_a + P_b + P_c + \dots$$

or

$$P_{\text{total}} = n_a RT/V + n_b RT/V + n_c RT/V + \dots$$

or

$$P_{\text{total}} = (n_a + n_b + n_c + \dots)RT/V$$

The pressure in a flask containing a mixture of 1 mole of 0.20 mole O₂ and 0.80 mole N₂ would be the same as the same flask holding 1 mole of O₂.

Partial pressures are useful when gases are collected by bubbling through water (displacement). The gas collected is saturated in water vapor which contributes to the total number of moles of gas in the container.

Non-Ideal Gases

The ideal gas equation ($PV=nRT$) provides a valuable model of the relations between volume, pressure, temperature, and number of particles in a gas. As an ideal model, it serves as a reference for the behavior of real gases. The ideal gas equation makes some simplifying assumptions which are obviously not quite true. Real molecules do have volume and do attract each other. All gases depart from ideal behavior under conditions of low temperature (when liquefaction begins) and high pressure (molecules are more crowded so the volume of the molecule becomes important). Refinements to the ideal gas equation can be made to correct for these deviations. The van der Waals equation for n moles of gas is:

$$\left(P + \frac{n^2 a}{V^2}\right)(V - nb) = nRT$$

See Table G-7

Table G-7 Empirically determined values for the constants a and b .

Molecule	a (liters ² -atm/mole ²)	b (liters/mole)
H ₂	0.2444	0.02661
O ₂	1.360	0.03183
N ₂	1.390	0.03913
CO ₂	3.592	0.04267
Cl ₂	6.493	0.05622
Ar	1.345	0.03219
Ne	0.2107	0.01709
He	0.03412	0.02370

Finally, a *real gas*, as opposed to an *ideal gas*, refers to an assumption base where the following are taken into account: (i) compressibility effects, (ii) variable heat capacity, (iii) van der Waals forces, (iv) non-equilibrium thermodynamic effects, and (v) effects from molecular dissociation and elementary reactions with variable composition. For most applications, such a detailed analysis is unnecessary and the ideal gas approximation is used. Real-gas models have to be used (i) near the condensation point of gases, (ii) near the critical point, and (iii) at high pressure.

The units of pressure that are used are pascal (Pa), standard atmosphere (atm), and torr. 1 atm is the average pressure at sea level, which is normally used as a standard unit of pressure. The SI unit is the pascal, and 101,325 pascals equals 1 atmosphere (14.7 psi). A torr is the same unit as the mm Hg (millimeter of mercury; thus, 760 torr equals 1 atmosphere.

See also: Ideal Gas, Ideal Gas Law.

Gas Liquids

Gas liquids (in the case of natural gas, referred to as natural gas liquids, NGLs) are the hydrocarbon liquids that condense during the processing of hydrocarbon gases that are produced from (in the case of alternate energy sources) a thermal process. These are ethane (C_2H_6), propane (C_3H_8), normal butane ($n-C_4H_{10}$), isobutane ($i-C_4H_{10}$), pentanes (C_5H_{12}), and even higher molecular weight hydrocarbons. When processed and purified into finished by-products, all of these are collectively referred to as gas liquids (GLs).

The recovery of the gas liquids (GLs) is typically accomplished by a cryogenic low temperature distillation process involving expansion of the gas through a turbo-expander followed by distillation in a demethanizing fractionating column. Some gas processing plants use lean oil absorption process rather than the cryogenic turbo-expander process. The residue gas from the gas liquids recovery section is the final, purified sales gas which is pipelined to the end-user markets.

The recovered stream of gas liquids is processed through a fractionation train consisting of three distillation towers in series: a de-ethanizer, a depropanizer, and a debutanizer. The overhead product from the de-ethanizer is ethane, and the bottoms are fed to the depropanizer. The overhead product from the depropanizer is propane, and the bottoms are fed to the debutanizer. The overhead product from the debutanizer is a mixture of normal and iso-butane, and the bottoms product is a C_5+ mixture. The recovered streams of propane, butanes, and C_5+ are each "sweetened" in a Merox process unit to convert undesirable mercaptans (RSH) into disulfides (RSSR) and, along with the recovered ethane, are the final gas liquids by-products from the gas processing plant.

See also: Gas Cleaning, Gas Liquids – Fractionation, Gas Processing.

Gas Liquids – Fractionation

The bottom liquid from the gas liquids recovery plant may be sold as a mixed product. This is common for small, isolated plants where there is insufficient local demand. The mixed product is transported by truck, rail, barge, or pipeline to a central location for further processing. Often, it is more economical to fractionate the liquid into its various components, which have a market value as purity products.

At the fractionation plant, liquids will be separated into commercial quality products and then delivered to the market by tankers (exports) and tank trucks (domestic consumption). The gas liquids are fractionated by heating mixed gas liquid streams and passing them through a series of distillation towers. Fractionation takes advantage of the differing boiling points of the various products. As the temperature of the gas liquids stream is increased, the lightest (lowest boiling point) product boils off the top of the tower as a gas where it is then condensed into a purity liquid that is routed to storage. The heavier liquid mixture at the bottom of the first tower is routed to the second tower where the process is repeated, and a different product is separated and stored. This process is repeated until the gas liquids stream has been separated into their components.

Fractionators are usually named for the overhead or top product. Therefore, a de-ethanizer implies that the top product is ethane; a depropanizer indicates that the top product is propane. Gas liquids are normally fractionated by boiling the lighter products from the heavier products, and the process can be adapted for application to gas liquids from alternate energy sources (such as biomass).

The first step in the fractionating sequence is to separate the ethane and propane (in the de-ethanizer), with the ethane going overhead and the propane and heavier components passing from the bottom of the fractionator.

The next step in the processing sequence is to separate the propane and the isobutene (in the depropanizer), with the propane going overhead and the isobutane and heavier components passing from the bottom of the depropanizer. The next fractionating step uses a debutanizer in which the separation of the butanes from the pentanes plus C_5+ stream is achieved. The butanes (both iso-butane and n-butane) pass overhead and the pentanes plus from the bottom of the fractionator. When it is desirable to do so, the butanes which pass overhead from the debutanizer may be separated into iso-butane and n-butane in a butane splitter or de-isobutanizer. The iso-butane passes overhead, and the n-butane is drawn from the bottom of the tower.

Depending on the market situation of each product, the number of fractionating columns may be varied. For example, when a market for liquefied petroleum gas (LPG) only exists during a portion of the year, an LPG mixture

could be produced overhead with natural gasoline produced as bottoms in the second tower, and the third tower would be shut down and not operated.

Fractionation of the gas liquids to produce purity products such as petrochemical- grade ethane feedstock or fuel grade propane may take place in a gas processing facility but more commonly occurs at another location, usually a regional market center.

Gasohol

Gasohol is a mixture of 10% v/v anhydrous ethanol and 90% gasoline by volume; 7.5% anhydrous ethanol and 92.5% gasoline by volume; or 5.5% anhydrous ethanol and 94.5 percent gasoline by volume.

Ethanol (ethyl alcohol) and methanol (methyl alcohol) are two types of alcohol fuels. The use of pure alcohols in internal combustion engines is only possible if the engine is designed or modified for that purpose. However, in their anhydrous or pure forms, they can be mixed with gasoline in various ratios for use in unmodified automobile engines. Typically, only ethanol is used widely in this manner, particularly since methanol is toxic.

E10, sometimes called gasohol, is a fuel mixture of 10% ethanol and 90% gasoline that can be used in the internal combustion engines of most modern automobiles. E10 blends are typically rated as 2 to 3 octane higher than regular gasoline and are approved for use in all new US automobiles, and are mandated in some areas for emissions and other reasons. E10 and other blends of ethanol are considered to be useful in decreasing US dependence on foreign oil, and can reduce carbon monoxide (CO) emissions by 20 to 30% under the right conditions. Although E10 does decrease emissions of CO and greenhouse gases such as carbon dioxide by an estimated 2% over regular gasoline, it can cause increases in evaporative emissions and some pollutants depending on factors like the age of the vehicle and weather conditions.

Similar blends include E5 and E7. These concentrations are generally safe for recent engines that run on pure gasoline. Some regions and municipalities mandate that the locally-sold fuels contain limited amounts of ethanol. One way to measure alternative fuels in the United States is the gasoline-equivalent gallons (GEG).

E15 contains 15% ethanol and 85% gasoline. This is generally the greatest ratio of ethanol to gas that is recommended by auto manufacturers that sell vehicles in the United States, though it is possible that many vehicles can handle higher mixtures without trouble. Flexible-fuel vehicles (FFV) are designed to take higher concentrations, up to 96% v/v ethanol (and no gasoline).

E85 is a mixture of 85% ethanol and 15% gasoline, and is generally the highest ethanol fuel mixture found in the United States. This mixture has an octane rating of approximately 105. This is down significantly from pure ethanol but still much higher than normal gasoline 87 octane. The addition of a small amount of gasoline helps a conventional engine start when using this fuel under cold conditions. E85 does not always contain exactly 85% ethanol. In winter, especially in colder climates, additional gasoline is added (to facilitate cold start).

E95 designates a blend of 95% ethanol and 5% ignition improver and is used in some diesel engines where high compression is used to ignite the fuel, as opposed to the operation of gasoline engines where spark plugs are used. Because of the high ignition temperatures of pure ethanol, the addition of ignition improver is necessary for successful diesel engine operation.

E100 is ethanol with up to 4% water. Operation in ambient temperatures below 15°C (59°F) causes problems with pure ethanol for starting engines. The most common cold weather solution is to add an additional small gasoline reservoir to increase the gasoline content momentarily to permit starting the engine. Once started, the engine is then switched back to pure ethanol.

Gas Oil

Gas oil is a liquid crude oil distillate with a viscosity and boiling range between kerosene and lubricating oil (230 to 260°C, 450 to 500°F). Gas oil boils between the kerosene and lubricating oil fractions and is used to produce diesel fuel and heating oil.

Distillation (fractionation) separates shale oil into groups only by their boiling-point ranges; impurities may remain. These include organic compounds containing sulfur, nitrogen, and oxygen, inorganic salts, and dissolved metals that were present in the crude feedstock.

The gas streams may contain constituents that might be otherwise fractionated into middle distillates (fuel oils) and lubricating oil. Vacuum distillation will also produce low-boiling vacuum gas oil and high-boiling vacuum gas oil as well as vacuum residuum. Generally, the vacuum gas oil streams are sent to the catalytic cracker to produce more gasoline streams.

Analogous to crude oil, shale oil can be distilled as a single (unblended) feedstock or as a blend with crude oil.

The feedstock is heated in a heat exchanger and furnace to approximately 750°F and fed to a vertical, distillation column at atmospheric pressure where most of the feed is vaporized and separated into its various fractions by condensing on 30 to 50 fractionation trays, each corresponding to a different condensation temperature. The lower-boiling (lower-boiling) fractions condense and are collected toward the top of the column, whereas higher-boiling (heavier) fractions, which may not vaporize in the column, are further separated later by vacuum distillation.

The distillation section comprising the atmospheric unit and the vacuum unit is required to have the greatest flexibility in terms of variable quality of feedstock and range of product yields. The atmospheric distillation unit is, in fact, a collection of distillation units that enable a fairly efficient degree of fractionation to be achieved. In contrast to the early units, which consisted of separate stills, a tower is used in the modern-day refinery.

Vacuum distillation evolved because of the need to separate the less volatile products, such as lubricating oils, from the crude oil without subjecting these high boiling products to cracking conditions. The boiling range of the highest boiling fraction obtainable at atmospheric pressure is limited by the temperature (approximately 350°C; ca. 660°F) at which the residue starts to decompose or crack, unless cracking distillation is preferred. When the feedstock is required for the manufacture of lubricating oils, further fractionation without cracking is desirable and this can be achieved by distillation under vacuum (reduced pressure) conditions.

See also: Refining.

Gasoline

Gasoline, also called gas (United States and Canada), or petrol (Great Britain) or benzine (Europe) is mixture of volatile, flammable liquid hydrocarbons derived from crude oil and used as fuel for internal-combustion engines. It is also used as a solvent for oils and fats. Originally a by-product of the crude oil industry (kerosene being the principal product), gasoline became the preferred automobile fuel because of its high energy of combustion and capacity to mix readily with air in a carburetor. Small quantities of various additives are common, for purposes such as tuning engine performance or reducing harmful exhaust emissions. Some mixtures also contain ethanol as a partial alternative fuel. In aviation, mogas, short for motor gasoline, is used to distinguish automobile fuel from aviation gasoline, or avgas.

Gasoline is a mixture of hydrocarbons that usually boil below 180°C (355°F) or, at most, below 200°C (390°F). The hydrocarbon constituents in this boiling range are those that have four to twelve carbon atoms in their molecular structure and fall into three general types: paraffins (including the cycloparaffins and branched materials), olefins, and aromatics. Gasoline is produced in a refinery as a blend of several streams. Initially, the fraction that is separated from crude oil by distillation (straight-run gasoline or straight-run naphtha) does not meet the required specifications for modern engines (in particular octane rating), but will form part of the blend. The various refinery streams blended together to make gasoline all have different characteristics. Some of the streams which contribute to the final gasoline product are:

1. Straight-run naphtha (referred to as virgin naphtha), which is produced directly from crude oil by distillation but has a low octane rating, low aromatics (depending on the crude oil), some naphthene derivatives (cycloalkane derivatives) and no olefin derivatives (alkene derivatives).

2. Gasoline from a catalytic cracking unit (FCC gasoline, cat gasoline) or cat cracked naphtha (FCC naphtha, cat naphtha), which is produced in a catalytic cracker, with a moderate octane rating, high olefin (alkene) content, and moderate aromatics level.
3. Hydrocrackate (high-, mid-, and low-boiling), which is produced in a hydrocracker, with medium-to-low octane rating and moderate-to-low levels of aromatics.
4. Reformate, produced in a catalytic reformer, with a high octane rating and high aromatic content, and low olefin (alkene) content.
5. Alkylate, produced in an alkylation unit, with a high octane rating and which is a pure paraffin (alkane) mix with branched chains.
6. Isomerase, which is obtained by isomerizing the pentane and hexane in low-boiling straight-run naphtha to yield their higher octane isomers.
7. Polymerase, which is obtained by the conversion of gaseous olefins, such as ethylene, propylene, and butylene into larger molecules in the gasoline range.

A typical gasoline is predominantly a mixture of paraffin derivative, naphthene derivatives (cycloalkane derivatives), and olefin derivatives (alkene derivatives). The exact ratios can depend on (i) the refinery where the gasoline is produced – not all refineries have the same suite of processing units, (ii) the feedstock used by the refinery, and (iii) the grade of gasoline, in particular the octane rating. Many countries set limits on the amount of aromatics in gasoline, benzene in particular, and olefin (alkene) content. This is increasing the demand for high octane pure paraffin (alkane) components, such as alkylate, and is forcing refineries to add processing units to reduce the benzene content.

Gasoline is highly volatile as measured by the Reid vapor pressure (RVP). The desired volatility depends on the ambient temperature: in hotter climates, gasoline components of higher molecular weight (lower volatility) are used. In hot climates, excessive volatility results in vapor lock where combustion fails to occur, because the liquid fuel has changed to a gaseous fuel in the fuel lines, rendering the fuel pump ineffective and starving the engine of fuel. This effect mainly applies to engine-mounted fuel pumps; a fuel pump located in the fuel tank, as in most modern automobiles, is much more resistant to vapor lock.

In cold climates, too little volatility results in cars failing to start; consequently, butane is often added to gasoline scheduled for use in coal climates.

An important characteristic of gasoline is its octane rating, which is a measure of how resistant gasoline is to the abnormal combustion phenomenon known as pre-detonation (also known as knocking, pinging, spark knock, and other names). Octane rating is measured relative to a mixture of 2,2,4-trimethylpentane and n-heptane. There are a number of different conventions for expressing the octane rating; therefore, the same fuel may be labeled with a different number, depending upon the system used.

Gas Processing

Gas cleaning (gas processing, gas refining) typically involves several processes to remove (i) oil; (ii) water; (iii) elements such as sulfur, helium, and carbon dioxide; and (iv) gas liquids. In addition, it is often necessary to install scrubbers and heaters at or near the wellhead that serve primarily to remove sand and other large-particle impurities. The heaters ensure that the temperature of the gas stream does not drop too low and form a hydrate with the water vapor content of the gas stream.

Many chemical processes are available for gas cleaning. However, there are many variables in the choice of process or the choice of reining sequence that dictate the choice of process or processes to be employed. In this choice, several factors must be considered such as (i) the types and concentrations of contaminants in the gas, (ii) the degree of contaminant removal desired, (iii) the selectivity of acid gas removal required, (iv) the temperature, pressure, volume, and composition of the gas to be processed, (v) the carbon dioxide-hydrogen sulfide ratio in the gas, and (vi) the desirability of sulfur recovery due to process economics or environmental issues.

In addition to hydrogen sulfide and carbon dioxide, gas may contain other contaminants, such as mercaptans (also called thiols, R-SH) and carbonyl sulfide (COS). The presence of these impurities may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. However, these processes are also capable of removing the acid gas impurities to low levels when the acid gases are there in low-to-medium concentrations in the gas.

Process selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes remove both hydrogen sulfide and carbon dioxide; other processes are designed to remove hydrogen sulfide only. It is important to consider the process selectivity for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream.

See also: Gas Cleaning.

Gas Processing – Chemical Activators

A series of chemical activators used with methyl diethanolamine offers the most cost-effective answer to complete or controlled acid gas removal from sour to very sour gas streams. However, there are limitations of even the most advanced activated methyl diethanolamine only-based gas treatment technologies in handling very highly acid gas loaded natural or associated oil field gases, especially for bulk acid gas removal when the acid gases are destined for cycling and/or disposal by re-injection.

See also: Gas Cleaning, Gas Purification.

Gas Processing – Process Selection

Natural gas found at the wellhead, although still composed primarily of methane, is by no means as pure and must go through a series of processing or refining operations. Major transportation pipelines usually impose restrictions on the make-up of the gas that is allowed into the pipeline. That means that before the gas can be transported, it must be purified, while the ethane, propane, butane, and pentane derivatives must be removed from the gas stream.

Gas cleaning consists of separating all of the various hydrocarbon derivatives, non-hydrocarbon derivatives, and fluids from the gas stream. Although the processing of natural gas is in many respects less complicated than the processing and refining of crude oil, it is equally as necessary before its use by end users. The natural gas used by consumers is composed almost entirely of methane.

Raw natural gas comes from three types of wells: oil wells, gas wells, and condensate wells. Natural gas that comes from oil wells is typically termed associated gas. This gas can exist separate from oil in the formation (free gas), or dissolved in the crude oil (dissolved gas). Natural gas from gas and condensate wells, in which there is little or no crude oil, is termed non-associated gas. Gas wells typically produce raw natural gas by itself, while condensate wells produce free natural gas along with a semi-liquid hydrocarbon condensate. Whatever the source of the natural gas, once separated from crude oil (if present), it commonly exists in mixtures with other hydrocarbon derivatives, principally ethane, propane, butane, and pentanes. In addition, raw natural gas contains water vapor, hydrogen sulfide (H_2S), carbon dioxide, helium, nitrogen, and other compounds. In fact, associated hydrocarbon derivatives, known as natural gas liquids (NGLs), can be valuable by-products of natural gas processing. Natural gas liquids include ethane, propane, butane, iso-butane, and natural gasoline that are sold separately and have a variety of different uses, including enhancing oil recovery in oil wells, providing raw materials for oil refineries or petrochemical plants, and as sources of energy.

High partial pressures (50 psia) of acid gases enhance the probability of using a physical solvent. The presence of significant quantities of high-boiling hydrocarbon derivatives in the feed discourages using physical solvents. Low partial pressures of acid gases and low outlet specifications generally require the use of amines for adequate treating.

Process selection is not easy, and a number of variables must be weighed prior to making a process selection. After preliminary assessment, it usually requires a study of relevant alternatives.

In general, the batch and amine processes are used for over 90% of all onshore wellhead applications. Amine processes are preferred when the lower operating cost, the chemical cost for this process, is prohibitive, and justifies the higher equipment cost. The key is the sulfur content of the feed gas where below 20-pound sulfur per day, batch processes are more economical, and over 100-pound sulfur per day amine solutions are preferred.

Gas Purification

Gas purification is the treatment of coal gas to remove contaminants such as fly ash, tars, oils, ammonia, and hydrogen sulfide. Some gas streams, while ostensibly being hydrocarbon in nature, may contain large amounts of acid gases such as hydrogen sulfide and carbon dioxide. Most commercial plants employ hydrogenation to convert organic sulfur compounds into hydrogen sulfide. Hydrogenation is effected by means of recycled hydrogen-containing gases or external hydrogen over a nickel molybdate or cobalt molybdate catalyst.

In summary, refinery process gas, in addition to hydrocarbon derivatives, may contain other contaminants, such as carbon oxides (CO_x , where $x = 1$ and/or 2), sulfur oxides (SO_x , where $x = 2$ and/or 3), as well as ammonia (NH_3), mercaptans (R-SH), and carbonyl sulfide (COS).

The presence of these impurities may eliminate some of the sweetening processes, since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes not designed to remove (or incapable of removing) large amounts of acid gases whereas they are capable of removing the acid gas impurities to low levels when the acid gases are present only in low-to-medium concentration in the gas.

The processes that have been developed to accomplish gas purification vary from a simple once-through wash operation to complex multi-step recycling systems. In many cases, the process complexities arise because of the need for recovery of the materials used to remove the contaminants or even recovery of the contaminants in the original, or altered, form.

See also: Gas Cleaning.

Gas Streams

The processes that have been developed to accomplish gas purification vary from a simple once-through wash operation to complex multi-step recycling systems. In many cases, the process complexities arise because of the need for recovery of the materials used to remove the contaminants or even recovery of the contaminants in the original, or altered, form.

There are many variables in treating gas streams. The precise area of application of a given process is difficult to define, and it is necessary to consider several factors, which are (i) the types of contaminants in the gas stream, (ii) the concentration of each contaminant in the gas stream, (iii) the degree of contaminant removal desired (iv) the selectivity of acid gas removal required, (v) the temperature of the gas stream to be processed, (vi) the pressure of the gas stream to be processed, (vii) the volume of the gas stream to be processed, (viii) the composition of the gas to be processed, (ix) the carbon dioxide-hydrogen sulfide ratio in the gas, and (x) the desirability of sulfur recovery due to process economics or environmental issues.

In addition to hydrogen sulfide (H_2S) and carbon dioxide (CO_2), the gas stream may contain other contaminants, such as mercaptans (RSH) and carbonyl sulfide (COS) (Table G-8). The presence of these impurities may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. However, these processes are also capable of removing the acid gas impurities to low levels when the acid gases are there in low-to-medium concentrations in the gas.

Table G-8 Nomenclature of relevant properties of the various gas streams*.

Gas	Relevant property
Biogas	Gas produced from a biological source; also referred to as biogas
Blue water gas	Higher heat content (calorific value) gas produced from coal
Casinghead gas	Gas extracted from an oil well by separation at the surface.
Carbureted water gas	Higher heat content (calorific value) gas produced from coal
Coalbed methane	Gas from coal seams
Dry gas	High methane content
High-Btu gas	High energy gas; also called high heat-content gas
Landfill gas	Gas produced by the decay of organic matter in a landfill
Lean gas	High methane content
Low-Btu gas	Low energy gas; also called low heat-content gas
Medium-Btu gas	Medium energy gas; also called medium heat-content gas
Producer gas	Very low heat content (calorific value) gas produced from coal
Residue gas	Gas remaining after the condensing process; predominantly methane
Sour gas	High concentration of hydrogen sulfide (H_2S)
Sweet gas	Low concentration of hydrogen sulfide or no hydrogen sulfide
Synthesis gas	A mixture of carbon monoxide and hydrogen
Wet gas	High concentration of higher-boiling hydrocarbon derivatives (C_5 to C_{10})
Wood gas	Gas produced from wood

*Listed alphabetically.

Process selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes remove both hydrogen sulfide and carbon dioxide; other processes are designed to remove hydrogen sulfide only. It is important to consider the process selectivity for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream. Gas processing involves the use of several different types of processes, but there is always overlap between the various processing concepts. In addition, the terminology used for gas processing can often be confusing and/or misleading because of the overlap (Nonhebel, 1964; Curry, 1981; Maddox, 1982). There are four general processes used for emission control (often referred to in another, more specific context as flue gas desulfurization: (i) adsorption, (ii) absorption, (iii) catalytic oxidation, and (iv) thermal oxidation (Soud and Takeshita, 1994).

Adsorption is a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. Usually, carbon is the adsorbing medium, which can be regenerated upon desorption. The quantity of material adsorbed is proportional to the surface area of the solid and, consequently, adsorbents are usually granular solids with a large surface area per unit mass. Subsequently, the captured gas can be desorbed with hot air or steam, either for recovery or for thermal destruction.

Adsorbing units (adsorbers) are widely used to increase a low gas concentration prior to incineration unless the gas concentration is high in the inlet air stream. Adsorption also is employed to reduce problem odors from gases. There are several limitations to the use of adsorption systems, but it is generally felt that the major one is the requirement for minimization of particulate matter and/or condensation of liquids (e.g., water vapor) that could mask the adsorption surface and drastically reduce its efficiency.

Absorption differs from adsorption, in that it is not a physical-chemical surface phenomenon, but an approach in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). The process depends only on physical solubility and may include chemical reactions in the liquid phase (chemisorption). Common absorbing media used are water, aqueous amine solutions, caustic, sodium carbonate, and nonvolatile hydrocarbon oils, depending on the type of gas to be absorbed. Usually, the gas-liquid contactor designs which are employed are plate columns or packed beds.

Absorption is achieved by dissolution (a physical phenomenon) or by reaction (a chemical phenomenon). Chemical adsorption processes adsorb sulfur dioxide onto a carbon surface where it is oxidized (by oxygen in the flue gas) and absorbs moisture to give sulfuric acid impregnated into and on the adsorbent. Liquid absorption processes (which usually employ temperatures below 50°C (120°F) are classified either as physical solvent processes or chemical solvent processes. The former processes employ an organic solvent, and absorption is enhanced by low temperatures, or high pressure, or both. Regeneration of the solvent is often accomplished readily. In chemical solvent processes, absorption of the acid gases is achieved mainly by use of alkaline solutions such as amines or carbonates. Regeneration (desorption) can be achieved by the use of reduced pressures and/or high temperatures, whereby the acid gases are stripped from the solvent.

Solvents used for emission control processes should have: (i) a high capacity for acid gas, (ii) a low tendency to dissolve hydrogen, (iii) a low tendency to dissolve low-molecular-weight hydrocarbon derivatives, (iv) low vapor pressure at operating temperatures to minimize solvent losses, (v) low viscosity, (vi) low thermal stability, (vii) absence of reactivity toward gas components, (viii) low tendency for fouling, (ix) low tendency for corrosion, and (x) economically acceptable.

Amine washing of gas emissions involves chemical reaction of the amine with any acid gases with the liberation of an appreciable amount of heat, and it is necessary to compensate for the absorption of heat. Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) have been used in commercial applications.

The chemistry can be represented by simple equations for low partial pressures of the acid gases:

At high acid gas partial pressure, the reactions will lead to the formation of other products:

The reaction is extremely fast, the absorption of hydrogen sulfide being limited only by mass transfer; this is not so for carbon dioxide.

Regeneration of the solution leads to near complete desorption of carbon dioxide and hydrogen sulfide. A comparison between monoethanolamine, diethanolamine, and diisopropanolamine shows that monoethanolamine is the cheapest of the three but shows the highest heat of reaction and corrosion; the reverse is true for diisopropanolamine.

Carbonate washing is a mild alkali process for emission control by the removal of acid gases (such as carbon dioxide and hydrogen sulfide) from gas streams and uses the principle that the rate of absorption of carbon dioxide by potassium carbonate increases with temperature. It has been demonstrated that the process works best near the temperature of reversibility of the reactions:

Water washing, in terms of the outcome, is analogous to washing with potassium carbonate, and it is also possible to carry out the desorption step by pressure reduction. The absorption is purely physical, and there is also a relatively high absorption of hydrocarbon derivatives, which are liberated at the same time as the acid gases.

In chemical conversion processes, contaminants in gas emissions are converted to compounds that are not objectionable or that can be removed from the stream with greater ease than the original constituents. For example, a number of processes have been developed that remove hydrogen sulfide and sulfur dioxide from gas streams by absorption in an alkaline solution.

Catalytic oxidation is a chemical conversion process that is used predominantly for destruction of volatile organic compounds and carbon monoxide. These systems operate in a temperature regime of 205 to 595°C (400 to 1,100°F) in the presence of a catalyst. Without the catalyst, the system would require higher temperatures. Typically, the catalysts used are a combination of noble metals deposited on a ceramic base in a variety of configurations (e.g., honeycomb-shaped) to enhance good surface contact.

Catalytic systems are usually classified on the basis of bed types such as fixed bed (or packed bed) and fluid bed (fluidized bed). These systems generally have high destruction efficiencies for most volatile organic compounds, resulting in the formation of carbon dioxide, water, and varying amounts of hydrogen chloride (from halogenated hydrocarbon derivatives). The presence in emissions of chemicals such as heavy metals, phosphorus, sulfur, chlorine, and most halogens in the incoming air stream act as poison to the system and can foul up the catalyst.

Thermal oxidation systems, without the use of catalysts, also involve chemical conversion (more correctly, chemical destruction) and operate at temperatures in excess of 815°C (1,500°F), or 220 to 610°C (395 to 1,100°F) higher than catalytic systems.

Historically, particulate matter control (dust control) has been one of the primary concerns of industries, since the emission of particulate matter is readily observed through the deposition of fly ash and soot as well as in impairment of visibility. Differing ranges of control can be achieved by use of various types of equipment. Upon proper characterization of the particulate matter emitted by a specific process, the appropriate piece of equipment can be selected, sized, installed, and performance tested. The general classes of control devices for particulate matter are as follows:

Cyclone collectors are the most common of the inertial collector class. Cyclones are effective in removing coarser fractions of particulate matter. The particle-laden gas stream enters an upper cylindrical section tangentially and proceeds downward through a conical section. Particles migrate by centrifugal force generated by providing a path for the carrier gas to be subjected to a vortex-like spin. The particles are forced to the wall and are removed through a seal at the apex of the inverted cone. A reverse-direction vortex moves upward through the cyclone and discharges through a top center opening. Cyclones are often used as primary collectors because of their relatively low efficiency (50-90% is usual). Some small-diameter high-efficiency cyclones are utilized. The equipment can be arranged either in parallel or in series to both increase efficiency and decrease pressure drop. However, there are disadvantages that must be recognized. These units for particulate matter operate by contacting the particles in the gas stream with a liquid. In principle, the particles are incorporated in a liquid bath or in liquid particles which are much larger and therefore more easily collected.

Fabric filters are typically designed with non-disposable filter bags. As the dusty emissions flow through the filter media (typically cotton, polypropylene, Teflon, or fiberglass), particulate matter is collected on the bag surface as a dust cake. Fabric filters are generally classified on the basis of the filter bag cleaning mechanism employed. Fabric filters operate with collection efficiencies up to 99.9%, although other advantages are evident. There are several issues that arise during use of such equipment.

Wet scrubbers are devices in which a countercurrent spray liquid is used to remove particles from an air stream. Device configurations include plate scrubbers, packed beds, orifice scrubbers, venturi scrubbers, and spray towers, individually or in various combinations. Wet scrubbers can achieve high collection efficiencies at the expense of prohibitive pressure drops.

Other methods include use of high-energy input venturi scrubbers or electrostatic scrubbers where particles or water droplets are charged, and flux force/condensation scrubbers where a hot humid gas is contacted with cooled liquid or where steam is injected into saturated gas. In the latter scrubber, the movement of water vapor toward the cold water surface carries the particles with it (diffusiophoresis), while the condensation of water vapor on the particles causes the particle size to increase, thus facilitating collection of fine particles.

The foam scrubber is a modification of a wet scrubber in which the particle-laden gas is passed through a foam generator, where the gas and particles are enclosed by small bubbles of foam.

Electrostatic precipitators operate on the principle of imparting an electric charge to particles in the incoming air stream, which are then collected on an oppositely charged plate across a high-voltage field. Particles of high resistivity create the most difficulty in collection. Conditioning agents such as sulfur trioxide (SO₃) have been used to lower resistivity.

Important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles). Techniques under study include the use of high-voltage pulse energy to enhance particle charging, electron-beam ionization, and wide plate spacing. Electrical precipitators are capable of efficiencies >99% under optimum conditions, but performance is still difficult to predict in new situations.

Gas-to-Commodity

The constituents of gas streams all useful in their own right. The higher paraffins are particularly valuable for a wealth of chemicals and polymer precursors such as acetic acid, formaldehyde, olefins, polyethylene, polypropylene, acrylonitrile, ethylene glycol, etc., as well as portable premium fuels, such as propane. In addition, methane can be converted via syngas to methanol, ammonia, syncrude, lubricant, or some precursor for chemicals manufacture, e.g., dimethyl ether (DME), urea, etc., and then used to make chemicals for export.

In the gas-to-commodity concept, the gas is converted to thermal or electrical power, which is then used in the production of the commodity, which is then sold, on the open market. It is the energy from the gas, heat via electricity or direct combustion, and not the components of the gas-to-liquids concept that is used. The gas energy is, in essence, transported via the commodity.

Gas-to-Liquids

The gas-to-liquids (GTL) technology involves the conversion of a gas stream (such as, for example, natural gas) to liquid fuels such as gasoline, jet fuel, and diesel fuel. In the process, the Fischer-Tropsch technology is used to combine hydrogen with carbon monoxide to form different liquid hydrocarbon derivatives which are further processed using different refining technologies into liquid fuels.

In gas-to-liquids (GTL) transport process, methane (as the example) is first mixed with steam and converted to syngas (mixtures of carbon monoxide and hydrogen, CO + H₂) by one of a number of routes using suitable new catalyst technology. The syngas is then converted into a liquid using a Fischer-Tropsch process (in the presence of a catalyst) or an oxygenation method (mixing syngas with oxygen in the presence of a suitable catalyst).

The Fischer-Tropsch process for natural gas involves conversion of methane to mixture of carbon monoxide and hydrogen (synthesis gas) from which hydrocarbon derivatives can be produced by a catalytic process:

The utility of the process is primarily in its role in producing liquid hydrocarbon derivatives from a carbonaceous feedstock which leads to possible end products including kerosene, naphtha, methanol, dimethyl ether (DME), alcohols, waxes, diesel fuel, and gasoline, with water or carbon dioxide produced as a by-product. Dimethyl ether is also used as a transportation fuel or power generation fuel as well as a chemical feedstock for the petrochemical industry.

Methanol is a gas-to-liquids option that has been in commission since the mid-1940s. While methanol produced from gas was originally a relatively inefficient conversion process, optimized technology has improved the efficiency. Methanol can be used in internal combustion engines as a fuel, but the current market for methanol as a fuel is limited, although the development of fuel cells for motor vehicles may change this. Methanol is best used as a basic chemical feedstock for the manufacture of plastics. Methanol is made from natural gas (methane) in a series of three reactions:

Steam reforming:

Water shift reaction:

Synthesis:

The methanol thus formed may be converted to gasoline by the Mobil process. First methanol is dehydrated to give dimethyl ether:

This is then further dehydrated over a zeolite catalyst, ZSM-5, to give a gasoline with 80% w/w (based on the organics in the product stream) C_{5+} hydrocarbon products. ZSM-5 is deactivated by a carbon build-up over time in converting methanol to gasoline. The catalyst can be re-activated by burning off the coke in a stream of hot [500 °C (930 °F)] air; however, the number of re-activation cycles is limited.

The technology can produce a variety of chemicals and fuels – of particular interest is its ability to yield large volumes of sulfur-free diesel fuel. The process involves reforming natural gas into synthesis gas (also referred to by the shorter name syngas) by combining the gas with steam, air, or oxygen, then converting the synthesis gas-to-liquid hydrocarbon derivatives through catalytic reaction, typically with an iron- or cobalt-based catalyst. The liquid products are hydrocracked and stabilized to create transportation fuels and chemicals.

Until recently, this process has not been competitive in the crude oil marketplace, although it had been used for political reasons in noncompetitive economies. Dramatic recent advances in gas-to-liquids technology focus on improved processes and catalysts, which are reducing costs enough to be more competitive with crude oil-based fuels, depending on gas costs and oil prices.

Gas-to-liquids (GTL) technology mounted on barges or offshore platforms could bring to market liquid transportation fuels from deep-water Gulf of Mexico sites without gas pipeline access. In Alaska, converted gas from the North Slope could be transported through the existing Trans-Alaska Pipeline System (TAPS), from Prudhoe Bay to Valdez, where tankers would deliver these liquids to market.

Fueling vehicles with fuel from a gas-to-liquids process fuel consumes fewer crude oil resources per distance traveled than with a conventional fuel derived from crude oil. In addition, gas-to-liquids technology can exploit biomass in addition to gas reserves and crude oil reserves. Extrapolating from this point, using biomass to create gas-to-liquids fuels will extend the lifetime of natural gas and crude oil reserves accordingly.

Gas-to-Power

The most common method to generate power from a gas stream (such as natural gas) uses gas turbine generators (GTGs), either in simple-cycle or combined-cycle configurations. Gas-turbine-based power generation has proven to be the lowest-life-cycle-cost alternative to date for large-scale electric power generation from gas streams.

The main energy forecasts identify natural gas as the fastest-growing primary energy source at a global level. As for most other regions of the world, the use of natural gas in power generation is seen as the main driver for this increase. The favorable economics of combined cycle gas turbine (CCGT) power plants, especially their relatively low capital intensity and high conversion efficiencies, make natural gas the fuel of choice for power generation.

Increasing import dependency has reawakened concerns related to security of supply. Another important issue is whether investments in new generating capacity are as high as forecasted. Until recently, prices in many wholesale electricity markets did not appear to justify any substantial new investments in generation plant.

Currently, much of the transported gas destination is fuel for electricity generation. Electricity generation at or near the reservoir source and transportation by cable to the destination(s) (gas-to-power, GTL) is possible.

Thus, for instance, offshore or isolated gas could be used to fuel an offshore power plant (may be sited in less hostile waters), which would generate electricity for sale onshore or to other offshore customers. Unfortunately, installing high-power lines to reach the shoreline appear to be almost as expensive as pipelines, so that gas-to-power could be viewed as defeating the purpose of an alternative cheaper solution for transporting gas. There is significant energy loss from the cables along the long distance transmission lines, more so if the power is AC rather than DC; additionally, losses also occur when the power is converted to DC from AC and when it is converted from the high voltages used in the transmission to the lower values needed by the consumers.

Some consider having the energy as gas that is sent to the consumers gives greater flexibility and better thermal efficiency, because the waste heat can be used for local heating and desalination. This view is strengthened by the economics as power generation uses approximately 1 million scf/day of gas for every 10 MW of power generated, so that even large generation capacity would not consume much of the gas from larger fields, and thus not generate large revenues for the gas producers. Nevertheless, gas-to-power has been an option much considered in the US for getting energy from the Alaskan gas and oil fields to the populated areas.

There are other practical considerations to note such as if the gas is associated gas, then if there is generator shut-down and no other gas outlet, the whole oil production facility might also have to be shut down, or the gas released to flare. Also, if there are operational problems within the generation plant, the generators must be able to shut down quickly (in around 60 s) to keep a small incident from escalating. Additionally, the shutdown system itself must be safe so that any plant that has complicated processes that requires a purge cycle or a cool-down cycle before it can shut down is clearly unsuitable. Finally, if the plant cannot shut down easily and/or be able to start up again quickly (perhaps in an hour), operators will be hesitant to ever shut down the process, for fear of financial retribution from the power distributors.

Gas-to-Solid

Gas can be transported as a solid, with the solid being gas hydrate. Changing natural gas into a hydrate form for cheaper transport gained attention in the early 1990s. Norwegian crude oil engineers first proposed the idea after comparing the transport economics of liquid natural gas to natural gas hydrates, knowing that hydrates could store large amounts of natural gas in a small space – more than 180 standard cubic feet of gas can be stored in one cubic foot of hydrate.

Natural gas hydrate is the product of mixing natural gas with liquid water to form a stable water crystalline ice-like substance. Natural gas hydrate transport is believed to be a viable alternative to liquefied natural gas or pipelines for the transportation of natural gas from source to demand.

Natural gas hydrates are created when natural gas constituents (methane, ethane, and propane) stabilize the physical structure of water to form a three-dimensional cage-like structure with the gas molecule trapped within the cages. A cage is made up of several water molecules held together by hydrogen bonds. The hydrates are formed from natural gas in the presence of liquid water provided the pressure is above and the temperature is below specified limits. The solids have a snow-like appearance and have properties that make them useful in many kinds of applications, including transportation and storage. Gas hydrates contain approximately 15% by weight and 85% by weight water and can contain up to 160 cubic meters of gas per cubic meter of solid hydrate. The exact numbers depend on the gas composition and the formation (production) pressure and temperature.

Vast quantities of gas hydrate have been found in permafrost and at the seabed in depths below 500 m (1,500 ft), and if properly exploited could become a major source of natural gas (therefore, a major energy source) in the next 50 years. On the other hand, natural gas hydrates are a pipeline nuisance and safety hazard, and require considerable care by the operators to ensure that they do not form as they can block pipelines if precautions, such as methanol injection, are not taken.

For gas transportation and/or storage, natural gas hydrates can be deliberately formed by mixing natural gas and water at 1,200 to 1,500 psi and 2 to 10°C. If the slurry is refrigerated to around -15°C, it decomposes very slowly at atmospheric pressure, so that the hydrate can be transported by ship to market in simple insulated under near adiabatic conditions. At the market, the slurry is melted back to gas and water by controlled warming for use after appropriate drying in electricity power generation stations or other requirements. The hydrate mixture yields up to 160 m³

of natural gas per ton of hydrate, depending on the manufacture process. The manufacture of the hydrate could be carried out using mobile equipment for onshore and ship for offshore using a floating production, storage, and offloading vessel with minimal gas processing (cleaning, etc.) prior to hydrate formation, which is attractive commercially.

The water can be used at the destination if there is water shortage, or returned as ballast to the hydrate generator and, since it is saturated with gas, will not take more gas into solution. Process operability of continuous production of hydrate in a large-scale reactor, long-term hydrate storage, and controlled regeneration of gas from storage have all been demonstrated.

The hydrate mixture can be stored at normal temperatures (0 to -10°C) and pressures (10 to 1 atmosphere) where 1 m^3 of hydrate should contain approximately 160 m^3 gas per m^3 of water. This concentration of gas is attractive as it is easier to produce, safer, and cheaper to store compared to the 200 m^3 per 1 m^3 of compressed gas (high pressure ca. 3,000 psig) or the 637 m^3 gas per 1 m^3 of liquefied natural gas (at the low temperatures of -116°C , -177°F).

Gas storage in hydrate form becomes especially efficient at relatively low pressures where substantially more gas per unit volume is contained in the hydrate than in the free state or in the compressed state when the pressure has dropped. When compared to the transportation of natural gas by pipeline or as liquefied natural gas, the hydrate concept has lower capital and operating costs for the movement of quantities of natural gas over adverse conditions. Thus, gas hydrate is effective for gas storage and transport as it eliminates low temperatures and the necessity of compressing the gas to high pressures. Dry hydrate pellets yield approximately 160 m^3 of gas at standard conditions from 1 m^3 of hydrate compared to the 637 m^3 per 1 m^3 of liquefied natural gas. This is a considerable volume penalty (and hence transport cost) if considered in isolation, but by using cheaper ships to transport the hydrate, the process could be economical.

Gas Treating

Gas treating, gas processing, and gas sweetening are terms used to describe the various processes for removal of certain contaminants, primarily hydrogen sulfide and carbon dioxide, from natural gas or hydrocarbon liquids. Other reasons to remove these contaminants include toxicity, corrosiveness, freezing problems, and control of the overall heating value of the natural gas.

Raw natural gas comes primarily from any one of three types of wells: crude oil wells, gas wells, and condensate wells. Natural gas that comes from crude oil wells is typically termed associated gas. This gas can exist separate from the crude oil in the underground formation, or dissolved in the crude oil. Natural gas from gas wells and from condensate wells, in which there is little or no crude oil, is termed non-associated gas. Gas wells typically produce only raw natural gas, while condensate wells produce raw natural gas along with low density liquid hydrocarbon called natural gas condensate (condensate, natural gasoline). Raw natural gas can also come from methane deposits in the pores of coal seams. Such gas is referred to as coalbed gas, and it is also called sweet gas because it is relatively free of hydrogen sulfide.

In addition to hydrogen sulfide and carbon dioxide, the sulfur acids, carbonyl sulfide, carbon disulfide, and the mercaptan family, when present in sufficient quantities, are also candidates for removal with specific amines.

In addition, refinery process off-gas streams, or sour gas, from the coker, catalytic cracking unit, hydrotreating units, and hydroprocessing units can contain high concentrations of hydrogen sulfide mixed with low-boiling refinery fuel gases. Before elemental sulfur can be recovered, the fuel gases (primarily methane and ethane) need to be separated from the hydrogen sulfide. This is typically accomplished by dissolving the hydrogen sulfide in a chemical solvent. Solvents most commonly used are amines, such as diethanolamine (DEA). Dry adsorbents such as molecular sieves, activated carbon, iron sponge, and zinc oxide are also used. In the amine solvent processes, diethanolamine solution or another amine solvent is pumped to an absorption tower where the gases are contacted and hydrogen sulfide is dissolved in the solution. The fuel gases are removed for use as fuel in process furnaces in other refinery operations.

There is a number of ways in which to configure the various unit processes used for gas treating. Initially, raw natural gas is commonly collected from a group of adjacent wells and is first processed at that collection point for removal of free liquid water and natural gas condensate. The condensate is usually then transported to an oil refinery and the water is disposed of as wastewater.

The raw gas is then pipelined to a gas treating plant where the initial purification is usually the removal of acid gases (hydrogen sulfide and carbon dioxide). There are many processes that are available for that purpose as shown in the flow diagram, but amine treating (olamine treating) is the process that was historically used. Newer processes,

based on the use of polymeric membranes to separate the carbon dioxide and hydrogen sulfide from the natural gas stream, have gained increasing acceptance.

The acid gases removed by olamine treating or membrane treating can then be routed into a sulfur recovery unit which converts the hydrogen sulfide in the acid gas into either elemental sulfur or sulfuric acid. There is a number of processes available for these conversions, but the Claus process is by far the most well-known for recovering elemental sulfur.

The tail gas from the Claus process is then processed in a tail gas treating unit (TGTU) to recover and recycle residual sulfur-containing compounds back into the Claus unit. Again, as shown in the flow diagram, there are a number of processes available for treating the Claus unit tail gas and for that purpose, a wet sulfuric acid process is also very suitable since it can work autothermal on tail gases.

The next step in the gas processing plant is to remove water vapor from the gas using either the regenerable absorption in liquid triethylene glycol (TEG) (glycol dehydration) or a pressure swing adsorption unit which is regenerable adsorption using a solid adsorbent. Mercury is then removed by using adsorption processes such as activated carbon or regenerable molecular sieves.

Nitrogen is next removed and rejected using one of three processes which are (i) a cryogenic process using low temperature distillation, which can be modified to also recover helium, if desired, (ii) an absorption process using lean oil or a solvent as the absorbent, and (iii) an adsorption process using activated carbon or molecular sieves as the adsorbent. This process may incur the loss of butanes and heavier hydrocarbon derivatives.

The next step is to recover the natural gas liquids (NGL) for which most large, modern gas processing plants use another cryogenic low temperature distillation process involving expansion of the gas through a turbo-expander followed by distillation in a demethanizing fractionating column. Some gas processing plants use lean oil absorption process rather than the cryogenic turbo-expander process.

The residue gas from the section where the natural gas liquids are recovered is the final, purified sales gas, which is pipelined to the end-user markets.

The recovered stream of natural gas liquids is processed through a fractionation train consisting of three distillation towers in series which are (i) a de-ethanizer, which removes ethane, (ii) a depropanizer, which removes propane, and (iii) a debutanizer, which removes butane.

The overhead product from the de-ethanizer is ethane, and the bottoms are fed to the depropanizer. The overhead product from the depropanizer is propane, and the bottoms are fed to the debutanizer. The overhead product from the debutanizer is a mixture of normal and iso-butane, and the bottoms product is a C5+ mixture. The recovered streams of propane, butanes, and C5+ are each sweetened (freed of odiferous sulfur compounds) in a Merox process unit to convert undesirable and odiferous mercaptans (RSH) into disulfides (SSR) and, along with the recovered ethane, are the final natural gas liquids by-products from the gas treating plant.

Geochemical Cycles

A developmental path followed by individual elements or groups of elements in the crustal and sub-crustal zones of the Earth and on its surface. The concept encompasses geochemical differentiation (natural separation and concentration of elements) and heat-assisted recombination processes. Changes may not be apparent over a short term, but over a long term, changes of great magnitude occur, including the evolution of continents and oceans. The carbon cycle (Figure G-1) is the geochemical cycle by which carbon is exchanged among the biosphere, exosphere, geosphere, hydrosphere, and atmosphere of the Earth.

The carbon cycle is usually thought of as four major reservoirs of carbon interconnected by pathways of exchange which are (i) plants, (ii) the terrestrial biosphere, which is usually defined to include fresh water systems and non-living organic material, such as soil carbon, (iii) the oceans, including dissolved inorganic carbon and living and non-living marine biota, and (iv) sediments including fossil fuels.

The annual movements of carbon, the carbon exchanges between reservoirs, occur because of various chemical, physical, geological, and biological processes. The ocean contains the largest active pool of carbon near the surface of the Earth, but the deep ocean part of this pool does not rapidly exchange with the atmosphere.

See also: Biogeochemical Cycles.

Geohydrology

Geohydrology (hydrogeology) is the branch of earth science, which deals with the occurrence and movement of subterranean water. It is the subdivision of the science of hydrology that deals with the water beneath the surface of the Earth. It is interdisciplinary in scope in that it involves the application of the physical, biological, and mathematical sciences. Because geohydrology deals with the occurrence and movement of water in an almost infinitely complex subsurface geologic environment, it is, in its most advanced state, one of the most complex of the sciences. On the other hand, many of its basic principles and methods can be understood readily and used in the solution of groundwater problems.

Geological Age

The Earth is believed to be between 4 and 5 billion years old. Geological age is most commonly measured in millions of years (Table G-9).

Table G-9 Illustration of the age of the earth and the subdivision of the years.

Era	Period	Epoch	Years ago x 10 ⁶ **
Precambrian	Precambrian		570
Paleozoic	Cambrian		510
	Ordovician		439
	Silurian		409
	Devonian		363
	Mississippian*		323
	Pennsylvanian*		290
	Permian		245
Mesozoic	Triassic		208
	Jurassic		146
	Cretaceous		65
Cenozoic	Tertiary	Paleocene	57
		Eocene	35
		Oligocene	23
		Miocene	5
		Pliocene	2
	Quaternary	Pleistocene	0.01
		Holocene	present

*The Mississippian and Pennsylvanian Periods are sometimes (collectively) referred to as the Carboniferous Period. The numbers in years indicate the beginning and the end of the Periods and Epochs.

Geosphere

The geosphere (also called the land systems) constitutes the terrestrial component of the systems of the Earth and encompass all processes and activities related to the human use of land, including, technological and organizational investments and arrangements, as well as the benefits gained from land and the unintended social and ecological outcomes of societal activities. Changes in land systems have large consequences for the local environment and human well-being and are at the same time pervasive factors of global environmental change. In more specific terms, the lithosphere refers to the minerals in the crust of the Earth whereas the term geosphere is often more broad in coverage and refers to the complex and variable mixture of minerals, organic matter, water, and air which make up the soil.

The land provides vital resources to society, such as food and fuel and many other ecosystem services that support production functions, regulate risks of natural hazards, or provide cultural services. By using the land, changes are the direct result of human decision making which range from local land owners decisions to national scale planning and trade agreements. The aggregate impact of many local land system changes has far-reaching consequences for the Earth system, that feedback on ecosystem services, human well-being, and decision making. As a consequence, land system change is both a cause and consequence of socio-ecological processes.

The term Earth system refers to the interacting physical, chemical, and biological processes that occur on the Earth. The system consists of the land, oceans, atmosphere, and poles. It includes the natural cycles of the Earth – the carbon, water, nitrogen, phosphorus, sulfur, and other cycles and deep Earth processes. In addition, life is also an integral part of the Earth system. Life affects the carbon, nitrogen, water, oxygen, and many other cycles and processes. Two other definitions include the terms global change and global climate change.

Global change refers to planetary-scale changes in the Earth system. More completely, the term global change encompasses planetary-scale changes to atmospheric circulation, ocean circulation, climate, the carbon cycle, the nitrogen cycle, the water cycle and other cycles, sea-ice changes, sea-level changes, food webs, biological diversity, pollution, health, fish stocks, and more. Global climate change refers to the long-term average of the aggregation of all components of weather of the components of the climate of the Earth: precipitation, temperature, and cloudiness, for example. The climate system includes processes involving ocean, land, and sea ice in addition to the atmosphere. Many changes in Earth system functioning directly involve changes in climate. However, the Earth system includes other components and processes, biophysical and human, that are important for its functioning. Some Earth system changes, natural or driven by humans, can have significant consequences involving changes in climate.

The lithosphere is outermost shell of the Earth that is composed of the crust and the portion of the upper mantle that behaves elastically on time scales of thousands of years or greater; defined on the mineralogy. The lithosphere is subdivided into tectonic plates which are the uppermost part of the lithosphere that chemically reacts to the atmosphere, the hydrosphere, and the biosphere through the soil-forming process (called the pedosphere) There are two types of lithosphere which are (i) the oceanic lithosphere, which is associated with the oceanic crust and exists in the oceanic basins and has a density of approximately of approximately 2.9 grams per cubic centimeter, and (ii) the continental lithosphere, which is associated with the continental crust and has a on the order of 2.7 grams per cubic centimeter.

The oceanic lithosphere consists mainly of a mafic mantle (mafic: an adjective describing a silicate mineral or igneous rock that is rich in magnesium and iron) crust and ultramafic mantle (over 90% mafic) and is denser than continental lithosphere. It thickens as it ages and moves away from the mid-ocean ridge. This thickening occurs by conductive cooling, which converts hot asthenosphere into lithospheric mantle. It was less dense than the asthenosphere for tens of millions of years, but after this becomes increasingly denser. The gravitational instability of mature oceanic lithosphere has the effect that when tectonic plates come together, oceanic lithosphere invariably sinks underneath the overriding lithosphere. New oceanic lithosphere is constantly being produced at mid-ocean ridges and is recycled back to the mantle at subduction zones, so oceanic lithosphere is much younger than its continental counterpart. The oldest oceanic lithosphere is approximately 170 million years old compared to parts of the continental lithosphere which are billions of years old.

On the other hand, the continental lithosphere (also called the continental crust) is the layer of igneous, sedimentary rock that forms the continents and the continental shelves. This layer consists mostly of granitic rock.

Continental crust is also less dense than oceanic crust, although it is considerably thicker. Approximately 40% of the surface of the Earth is covered by continental crust, but continental crust makes up approximately 70% v/v of the crust of the Earth. The continental crust is believed to have been derived from the fractional differentiation of oceanic crust over geologic time (hundreds of millions of years) and was primarily a result of volcanism and subduction.

The lithosphere is underlain by the asthenosphere, which is the weaker, hotter, and deeper part of the upper mantle. The lithosphere-asthenosphere boundary is defined by a difference in response to stress in which the lithosphere remains rigid for long periods of geologic time in which it deforms elastically and through brittle failure. On the other hand, the asthenosphere undergoes considerable deformation and accommodates strain through this deformation.

The term biosphere refers to living organisms and their environments on the surface of the Earth (Manahan, 1991). Included in the biosphere are all environments capable of sustaining life above, on, and beneath the surface of the Earth as well as in the oceans. Consequently, the biosphere includes virtually all of the water systems (the aquasphere, the hydrosphere) as well as portions of the atmosphere and the upper lithosphere (land systems).

In addition, there are relationships between the atmosphere, the water systems, the land systems, and the biosphere. These relationships are physical and are also caused by environmental forces. It is worth noting here that such relationships, perhaps not in this exact concept, were noted more than four centuries ago. Paracelsus (Philippus Aureolus Theophrastus Bombast von Hohenheim; 1493-1541) taught that the macrocosm (the heavens) and the microcosm (the Earth and all of the living creatures) were linked together and that the macrocosm directed the growth and development of the microcosm.

In the modern relationships between the atmosphere, the water systems, and the land systems, acid rain is the precipitation phenomena that incorporate anthropogenic acids (i.e., those acids which are the result of human activities) and other acidic materials. The deposition of acidic materials into the water systems and onto the land occurs in both wet and dry forms as rain, snow, fog, dry particles, and gases.

The effect of acid rain (acid deposition) on a particular ecosystem depends largely on the sensitivity of the ecosystem to the acid deposition. There is also the ability of the ecosystem to neutralize the acid as well as the concentration and composition of acid reaction products and the amount of acid added to the system.

Trace element is a term that refers to those elements that occur at low levels in a given system. The somewhat ambiguous term probably arose from the inadequacy of earlier analytical techniques – before modern methods such as atomic absorption, plasma emission, neutron-activation analysis, gas chromatography, and mass spectrometry extended the limits of detection to the low levels currently attainable. In many early investigations, it was only possible to detect the presence of an element, as it was said to be present at a trace level. A reasonable definition of a trace element is that the element occurs at a level of a few parts per million or less. The term trace substance is a more general definition that is applied to both elements and chemical compounds.

There are a variety of trace elements encountered in natural waters, some of which are the nutrients required for animal and plant life. Of these, many are essential at low levels but toxic at higher levels. This is typical for many substances in the aquatic environment, a point that must be kept in mind in judging whether a particular element is beneficial or detrimental. Some of these elements, such as lead or mercury, have such toxicological and environmental significance that they are discussed in detail in separate sections.

Some of the heavy metals are among the most harmful of the elemental pollutants. These metals include essential elements like iron as well as toxic metals like lead (Pb), cadmium (Cd), and mercury (Hg). Most of them have a tremendous affinity for sulfur and attack sulfur bonds in enzymes, thus immobilizing the enzymes. Protein carboxylic acid (-COOH) derivatives and amino (-NH₂) groups are also chemically bound by heavy metals. Cadmium, copper, lead, and mercury ions bind to cell membranes, hindering transport processes through the cell wall. Heavy metals may also precipitate phosphate compounds or catalyze their decomposition.

The geosphere includes the parts of Earth where life exists and extends from the deepest root systems of trees, to the dark environment of ocean trenches, to the rain forests and high mountaintops (sometimes referred to as the biosphere). Often, the Earth in terms of spheres – (i) the atmosphere is the layer of air that stretches above the lithosphere, (ii) the water on the surface of the Earth, in the ground, and in the air constitute the hydrosphere, and (iii) the solid surface layer of the Earth is the lithosphere.

An ecosystem is a community of living organisms in conjunction with the nonliving components of their environment (such as air, water, and mineral soil), interacting as a system. Ecosystems are controlled both by (i) external

factors and (ii) internal factors. External factors such as climate, the parent material that forms the soil, and topography control the overall structure of an ecosystem and the way things work within it, but are not themselves influenced by the ecosystem. Internal factors not only control ecosystem processes but are also controlled by them and are often subject to feedback loops. Other internal factors include disturbance, succession, and the types of species present. Although humans exist and operate within ecosystems, their cumulative effects are large enough to influence external factors like climate. An important aspect of the chemistry of the biosphere is the chemistry that occurs in the soil.

The soil itself is a complex mixture of inorganic chemicals – even before pollution occurs. Eight chemical elements comprise the majority of the mineral matter in soils. Of these eight elements, oxygen, a negatively-charged ion (anion) in crystal structures, is the most prevalent on both a weight and volume basis. The next most common elements, all positively-charged ions which, in decreasing order, are silicon, aluminum, iron, magnesium, calcium, sodium, and potassium. Ions of these elements combine in various ratios to form different minerals.

The most chemically active fraction of soils consists of colloidal clays and organic matter. Colloidal particles are so small (<0.0002 mm) that they remain suspended in water and exhibit a large surface area per unit weight. These materials also generally exhibit net negative charge and high adsorptive capacity. Several different silicate clay minerals exist in soils, but all have a layered structure. It is these clay minerals that act as adsorbents for inorganic pollutants (as well as organic pollutants).

The soil transports and moves water, provides refuge for bacteria and other fauna, and has many different arrangements of weathered rock and minerals. When soil and minerals weather over time, the chemical composition of soil also changes. However, many of the problems of soil chemistry problems are concerned with environmental sciences such as the accidental or deliberate disposal of chemicals. This can involve several physical chemical interactions that can cause changes to the soil (i) ion exchange, (ii) soil pH, (iii) sorption and precipitation, and (iv) oxidation-reduction reactions.

Ion exchange involves the movement of cations (positively charged elements such as calcium, magnesium, and sodium) and anions (negatively charged elements such as chloride, and compounds like nitrate) through the soils. More specifically, cation exchange is the interchanging between a cation in the solution of water around the soil particle, and another cation that is on the surface of the clay mineral.

A cation is a positively charged ion and most inorganic contaminants are cations, such as: ammonium (NH_4^+), calcium (Ca^{2+}), copper (Cu^{2+}), magnesium (Mg^{2+}), manganese (Mn^{2+}), potassium (K^+), and zinc (Zn^{2+}). These cations are in the soil solution and are in dynamic equilibrium with the cations adsorbed on the surface of clay and organic matter. It is the cation exchange interaction of ions with clay minerals in the soil that gave soil the ability of soil to adsorb and exchange cations with those in soil solution (water in soil pore space). The adsorption capacity of a clay minerals can cause a mixture of inorganic pollutants to physically transform when one or more constituents of the mixture adsorbs on to a clay mineral. In addition, the total amount of positive charges that the clay can absorb (the cation exchange capacity, CEC) impacts the rate of movement of the pollutants through the soil and the physical and chemical changes that can occur to the pollutants. For example, soil (i.e., clay) with a low cation exchange capacity is much less likely to retain pollutants and, furthermore, the soil (i.e., the clay) is less able to retain inorganic chemicals with the potential that the chemicals are released into the groundwater.

Soil pH is a commonly measured soil chemical property and is also one of the more informative properties since the data imply certain characteristics that might be associated with a soil. For example, the pH of soil is a measure of the acidity or alkalinity: values 0 to 7 indicate acidity, while values from 7 to 14 indicate alkalinity. Typically, the pH value for soil usually ranges from 4 to 10. The pH is an important property that is involved in plant growth, as well as understanding how rapidly reactions occur in the soil. For example, the element iron becomes less available to plants at higher alkalinity ($\text{pH} > 7$) which creates iron deficiency problems. Crops usually have optimal growth at pH values between 5.5 and 8, but the value depends on the crop. The pH of soil also affects the ability of organisms to feed on contaminants. Thus, any chemical spillage on to soil can seriously affect the overall chemistry of the soil and the ability of flora and fauna to survive.

The other principal variables affecting life in soil in the environment include moisture, temperature, and aeration, and the balance of these factors controls the abundance and activities of the floral and faunal inhabitants in the soil which in turn have a marked influence on the critical processes of soil aggregation retention of pollutants.

Soil water is usually derived from rainfall or some other form of overland flow. The amount of water that enters the soil is a function of soil structure which in turn is a function of texture and higher-order structure, i.e., aggregation (e.g., well-aggregated, porous soils allow greater infiltration). Larger pores created by root channels and animal burrows (ant tunnels and worm holes) as well as other types of macropores also greatly facilitate movement of water into and through the soil profile. This is why these soil animals are usually regarded as highly beneficial in soil and why some scientists often use the abundance of earthworms as an indicator of a healthy soil, though it should be remembered that highly fertile, productive soils do not always contain large numbers of earthworms and other soil faunal species.

Although soil is an inorganic matrix of metals and minerals, the main reason why the soil becomes contaminated is due to the presence of anthropogenic waste. This waste is typically (i) chemicals in one form or another that are not indigenous to the soil or (ii) chemicals that are indigenous chemicals that are deposited into the soil in amounts that exceed the natural abundance. The typical actions that lead to pollution of the soil by inorganic chemicals are (i) industrial activities, (ii) agricultural activities, (iii) waste disposal, and (iv) acid rain.

Industrial activities have been the biggest contributor to the soil pollution since the time of the *Industrial revolution*, especially since the amount of mining and manufacturing increased almost logarithmically in the 160 years immediately following 1800. Most industries are dependent on extracting minerals from the Earth, and the by-products have not been sent for disposal in a manner that can be considered safe. Thus, the industrial waste lingers in the soil surface for a long time and makes it unsuitable for use. At the same time, physical changes and chemical changes to the inorganic pollutant also occur for the better or for worse.

Agricultural activities have caused a rise in the use of inorganic chemicals since technology provided the means of producing inorganic pesticides and inorganic fertilizers. They are full of chemicals that are not produced in nature and cannot be broken down by it. These chemicals seep into the ground after they mix with water and slowly change the character of the soil by adsorption and by changing the acidity/alkalinity of the water in the soil. Other chemicals damage the composition of the soil and make it easier to erode by water and air.

Waste disposal has also been major cause for concern insofar as the manner of disposal is subject to scrutiny. While industrial waste is sure to cause contamination. This type of waste typically contains toxins and chemicals which are now seeping into the land and causing pollution of soil. Finally, acid rain is caused when sulfur-containing and nitrogen-containing chemicals present in the air mix up with the rain and fall back to the soil. The polluted (acidified) water has the ability to dissolve away some of the soil constituents and, more drastically, change the structure of the soil. This latter action could release pollutants that were adsorbed (and may have even remained adsorbed) and once released can find their way into groundwater.

Geothermal Energy

Geothermal energy is the heat that comes from the sub-surface of the earth. It is contained in the rocks and fluids beneath the crust of the Earth crust and can be found as far down to the hot molten rock, magma. The internal heat of the Earth is the thermal energy generated from radioactive decay and continual heat loss from formation of the Earth. The slow decay of radioactive particles in the core of the Earth, a process that happens in all rocks, produces geothermal energy. In terms of alternative energy, geothermal energy is the use of the Earth's internal heat for practical purposes and in particular to boil water for heating buildings or generating electricity. Geothermal energy is produced by tapping into the thermal energy created and stored within the earth. It is considered sustainable because that thermal energy is constantly replenished.

The geothermal energy of the crust of the Earth originates from the original formation of the planet (20%) and from the radioactive decay of minerals (80%). The geothermal gradient, which is the difference in temperature between the core of the planet and its surface, drives a continuous conduction of thermal energy in the form of heat from the core to the surface.

By way of explanation, the earth has four major parts or layers: (i) an inner core of solid iron that is approximately 1,500 miles in diameter, (ii) an outer core of hot molten rock called magma that is approximately 1,500 miles thick, (iii) a mantle of magma and rock surrounding the outer core that is approximately 1,800 miles thick, and (iv) a crust of solid rock that forms the continents and ocean floors that is 15 to 35 miles thick under the continents and 3 to

5 miles thick under the oceans, The crust of the Earth is broken into pieces called tectonic plates. Magma comes close to the earth's surface near the edges of these plates, which is where many volcanoes occur. The lava that erupts from volcanoes is partly magma. Rocks and water absorb heat from magma deep underground. The rocks and water found deeper underground have the highest temperatures.

The temperature of the inner core of the Earth is on the order of $6,000^{\circ}\text{C}$ ($10,800^{\circ}\text{F}$), and the temperature at the core-mantle boundary may reach a temperature in excess of $4,000^{\circ}\text{C}$ ($>7,200^{\circ}\text{F}$). The high temperature and pressure in interior of the Earth cause some rocks to melt and the solid mantle to behave plastically, resulting in portions of the mantle flowing upward since it is lighter than the surrounding rock. Rock and water are heated in the crust, sometimes up to 370°C (700°F).

Geothermal thermal energy is used to generate electricity typically via a well that is drilled into an underground reservoir of water that can be as hot as 370°C (700°F). At the surface, a turbine is turned using the trapped steam. Heat pumps are used to move fluids through pipelines buried underground at depths where the temperature does not change much and is delivered to a home or commercial building. During the summer, this pipeline can pull heat out of a building and uses cooler fluid to cool the building. Geothermal water is also found in geysers or hot springs on the surface of the Earth.

To produce power from geothermal energy, wells are dug a mile deep into underground reservoirs to access the steam and hot water there, which can then be used to drive turbines connected to electricity generators. There are three types of geothermal power plants which are (i) dry steam, (ii), flash, and (iii) binary. Dry steam is the oldest form of geothermal technology and takes steam out of the ground and uses it to directly drive a turbine. Flash plants use high-pressure hot water into cool, low-pressure water while binary plants pass hot water through a secondary liquid with a lower boiling point, which turns to vapor to drive the turbine.

Geothermal energy provides a clear, sustainable, environmentally friendly, and substantial resource. However, it also faces challenges in that geothermal plants generally are site-specific and limited to regions with accessible deposits of high temperature ground water; the completion of a geothermal plant takes significant time (four to eight years) versus the times for wind or solar, and there is a lack of transmission lines.

There are many benefits to using geothermal power. It is clean and nonpolluting. It does not require the consumption of fossil fuels, so it reduces dependence on foreign or domestic oil, and it reduces harmful emissions from burning these fuels. Geothermal plants do not destroy large tracts of land. They are efficient: A geothermal plant usually can produce more power than a fossil fuel-burning plant of the same size.

Geothermal plants are also reliable because they do not depend on external fuel sources; they can run twenty-four hours a day, every day of the year. This is not always possible with power plants that burn coal or oil, which must be transported from distant locations. Geothermal plants are not vulnerable to weather, natural disasters, strikes, political disturbances, or other events that can disrupt fuel supplies.

Geothermal plants, on many levels, are flexible. It is possible to build them of modular components and to add or adapt components as the need arises. This is usually not possible with fossil fuel-burning plants. Geothermal power plants are especially valuable in areas with small power grids or in cases where a power grid is in the process of expanding. Flexible geothermal plants can provide backup power while the rest of the grid is installed.

Geothermal energy is generally sustainable and renewable. The Earth generates heat constantly. Rainfall and snowmelt continuously replenish reservoirs, and returning used water to the underground reservoir maintains its pressure and heat so that the reservoir can be used for an indefinite period of time.

The major limitation of geothermal power is that it can only be implemented in areas where there is a ready supply of hot water underground. This limits its use to geologically active areas such as California, Iceland, Japan, and the rest of the Pacific Rim and other areas with a thin crust, an active mantle, and pockets of subterranean hot water. Only the hottest water can be used to generate electricity. Some places have naturally heated groundwater that is not hot enough to produce the steam needed to turn turbines. That water is still usable for other purposes but not as a workable power source.

It is possible to deplete a reservoir. If a geothermal reservoir runs out of water or grows too cool, it ceases to be useful, though this depletion can take decades or even centuries. For this reason, there are claims that geothermal energy is not actually a renewable resource.

Like solar power and wind power, geothermal energy is clean. Geothermal power plants do not have to burn fuels so they do not produce emissions of greenhouse gases or other pollutants, which means they do not contribute to

smog or global warming. They do emit small amounts of carbon dioxide, approximately 4% of the amount emitted by burning fossil fuels. Binary plants produce no emissions at all. Areas that have geothermal power plants tend to have much better air quality than those with fossil fuel-burning power plants.

A geothermal power plant can be small compared to other types of power plants, so it is not as disruptive to the landscape. It can be built right next to its geothermal well. There is no need to build dams, dig mines, cut down trees, or dispose of wastes, which are necessary with other common forms of power. It is actually possible to build geothermal power plants in the middle of farmland or forests without damaging the surrounding plants and animals. Even in areas where geothermal energy is not powerful enough to create electricity, people can still make use of local hot water for heating and bathing. This means they do not have to use electricity from other sources to heat their water, which can help save money and fuel.

There are some minor environmental drawbacks to using geothermal resources. Geothermal reservoirs sometimes contain hydrogen sulfide (H_2S) gas, which smells like rotten eggs and can be toxic at high concentrations. Geothermal power plants use scrubbers to remove this gas from emissions. Geothermal water also contains a high concentration of minerals, so geothermal wells must contain several layers of pipe and casings to prevent geothermal water from mixing with ordinary groundwater. Because geothermal power plants re-inject their used geothermal water back into the underground reservoir, in most cases, the geothermal water never gets near groundwater and cannot harm aquatic plants and animals.

The areas around geothermal power plants experience increased activity, such as small earthquakes, and there is a danger of landslides. Federal laws in the United States prohibit the construction of geothermal power plants in national parks, such as Yellowstone. However, the environmental problems associated with using geothermal energy are generally far less serious than those caused by using fossil fuels.

Geothermal heating has many obvious environmental benefits. It does not pollute the air at all because geothermal heating involves no combustion and therefore no emissions. Geothermal heat pumps pose few environmental problems. They use an antifreeze substance, but it is usually a nontoxic chemical called propylene glycol or small amounts of methanol, both of which are commonly used in windshield washing solutions.

Economically, geothermal heat can be much less expensive than other sources of heat, such as fossil fuels or wood, but that cost depends on several factors. The initial installation costs can be high, but if the heating system works well, it can pay for itself quickly. Geothermal heat works especially well in areas that already have wells dug into geothermal reservoirs. If there are already wells in place, a district or institution only needs to buy pipelines, heat exchangers, and pumps. A heating system is more expensive to install if there is not already a good geothermal reservoir in use.

Geothermal Energy – Electricity Generation

To produce electricity from a geothermal resource, wells are drilled into the reservoir, and as the hot, high-pressure water travels to surface of the Earth, some of it vaporizes into steam as the pressure decreases. The hotter the original source, the greater the amount of dry steam produced. For dry-steam sources, the technology is basically the same as for electric plants that use the burning of fossil fuels to produce steam, except that the temperature and pressure of the geothermal steam are much lower. Dry-steam fields are being used in the United States, Italy, and Japan. In the Geysers geothermal area in California, the steam temperature is approximately 200°C (390°F) and the pressure on the order of 100 psi.

For geothermal reservoirs that are at lower temperatures, and hence produce less dry steam, working plants usually employ multiple-vaporization systems. The first vaporization (“flash”) is conducted under some pressure, and the remaining pressurized hot water from the ground, along with the hot residual water from the turbine, can be flashed again to lower pressure, providing steam for a second turbine.

If the temperature of the original hot water is too low for effective flashing, the water can still be used to generate electricity in what is referred to as binary cycle (or organic cycle) electricity generation. The hot water is pumped to the surface under pressure to prevent evaporation, which would decrease the temperature, and its heat is transferred to an organic fluid such as isobutane, isopentane, or hexane, all of which have a boiling temperature lower than that

of water. The fluid is vaporized by the heat from the water and acts as the working fluid in a turbine. It has been estimated that geothermal reservoirs with temperatures suitable for binary cycle generation are approximately fifty times as abundant as sources that provide pure dry steam.

Some geothermal power plants use a combination of flash and binary cycles to increase the efficiency of electricity production. An initial flash creates steam that drives a turbine; then, the binary cycle is run, using either the hot water remaining after the initial flash or the hot exhaust from the turbine.

Geothermal Energy – Environmental Effects

Geothermal power plants are generally environmentally clean. They do not burn fossil fuels, so they help conserve those fuels for other purposes. They produce no emissions to contribute to air pollution, the greenhouse effect, or global climate change. There is no smoke surrounding geothermal power plants. Dry steam and flashed steam plants emit excess steam and small amounts of gases, while binary plants emit nothing at all because all the fluids are contained within the system and recycled.

Geothermal plants do not need space to store fuels, and they do not create large piles of ash that must be cleared or oil spills that damage oceans. They also do not pollute groundwater unless the geothermal water has a high concentration of minerals or metals. Unlike most other power plant types, geothermal plants do not require large amounts of space to function. They can be built right on top of geothermal reservoirs. The pumps that bring water up from geothermal reservoirs are small, especially compared to those used by coal mines or oil wells. They do not tear up large plots of land or destroy forests. There is no need to build major highways, railroads, or pipelines in order to transport fuel to geothermal power plants because their source of power is directly below them. It is actually possible to build geothermal power plants in the midst of farmland or forests, where they can coexist with livestock and wildlife.

The most important potential environmental impacts of geothermal energy are water and air pollution. At the largest geothermal plants, thousands of tons of hot water and/or steam are extracted per hour, and these fluids contain a variety of dissolved pollutants. The hot geothermal water dissolves salts from surrounding rocks, and this salt produces severe corrosion and scale deposits in equipment. To prevent contamination of surface water, the geothermal brine must either be returned to its source or discarded carefully in another area. In addition to salts, the geothermal waters sometimes contain high concentrations of toxic elements such as arsenic, boron, lead, and mercury.

Geothermal water often contains dissolved gases as well as salts and toxic elements. One of the gases that is often found in association with geothermal water and steam is hydrogen sulfide, which is toxic in high concentrations.

Geothermal brines also are a source of the greenhouse gas carbon dioxide, which contributes to global climate change. However, a typical geothermal electrical plant produces only approximately 5% of the carbon dioxide emitted by a fossil-fuel-fired plant generating the same amount of electricity. Many modern geothermal plants can capture the carbon dioxide (as well as the hydrogen sulfide) and reinject it into the geothermal source along with the used geothermal fluids. At these facilities, the carbon dioxide that escapes into the atmosphere is less than 0.1% of the emissions from a coal- or oil-fired plant of the same capacity.

Another potential problem, particularly if geothermal water is not returned to its source, is land subsidence. For example, there may be significant subsidence and another annoying difficulty with geothermal heat has been the noise produced by escaping steam and water. The shriek of the high-pressure fluids is intolerable, and is usually dissipated in towers in which the fluids are forced to swirl around and lose their kinetic energy to friction. However, the towers provide only partial relief, and the plants are still noisy.

Geothermal Gradient

The geothermal gradient is the rate of increase in temperature per unit depth in the Earth. It varies with location and is typically measured by determining the bottom open-hole temperature after borehole drilling.

For example, crude oil in an underground formation is much more fluid than it is on the surface and is generally mobile under reservoir conditions because the elevated temperatures (the geothermal gradient) in subterranean formations decrease the viscosity. Although the geothermal gradient varies from place to place, it is generally on the order of 25 to 30°C/km (15°F/1,000 ft or 120°C/1,000 ft, i.e., 0.015°C per foot of depth or 0.012°C per foot of depth).

In the geosciences, the measurement of temperature (T) is associated with heat flow (Q):

$$Q = K\Delta T/\Delta Z$$

K is the thermal conductivity of the rock.

Temperatures at the surface of the earth are controlled by the Sun and the atmosphere, except for areas such as hot springs and lava flows. From shallow depths to approximately 200 ft below the surface, the temperature is constant at approximately 11°C (55°F). In a zone between the near surface and approximately 400 feet (122 meters), the gradient is variable because it is affected by atmospheric changes and circulating groundwater. Below that zone, temperature almost always increases with depth. However, the rate of increase with depth (geothermal gradient) varies considerably with both tectonic setting and the thermal properties of the rock.

High gradients (up to 11°F/100 ft, or 200°C/km) are observed along the oceanic spreading centers (for example, the Mid-Atlantic Rift) and along island arcs (for example, the Aleutian chain). The high rates are due to molten volcanic rock (magma) rising to the surface. Low gradients are observed in tectonic subduction zones because of thrusting of cold, water-filled sediments beneath an existing crust. The tectonically stable shield areas and sedimentary basins have average gradients that typically vary from 0.82 to 1.65°F/100 ft (15 to 30°C/km).

The geothermal gradient is important for the oil, gas, and geothermal energy industries. Downhole logging tools must be hardened if they are to function in deep oil and gas wells in areas of high gradient. Calculation of geothermal gradients in the geological past is a critical part of modeling the generation of hydrocarbon derivatives in sedimentary basins.

Geothermal Heat Pumps

Geothermal heat pumps work by pumping water or a mix of water and antifreeze through the ground next to a house or building. The ground temperature remains relatively constant throughout the year, generally between 7 and 12°C (45 and 55°F). In winter, 7 and 12°C underground pipes absorb heat from the Earth. This heated water circulates into the heat pump, where it is concentrated so that it will increase to the desired room temperature. The heat pump then pumps the hot air through the ducts in the building, heating the rooms. In summer, the process is reversed; the hot air is sucked from the building and dispersed into the ground. The geothermal heat pump system uses ordinary ductwork, so there is no need to modify existing ducts.

Geothermal heat pumps usually can at least partially heat water for the home. This is not necessarily possible all year round. During the summer, the heat pump can use excess heat to warm domestic hot water, but during the winter, there is not as much heat available to warm the water. A home with a geothermal heat pump must usually have an alternate source of heat for water, but even so, using excess heat for even part of the year results in an energy savings. New technology is improving this situation; because geothermal heat pumps are so much more efficient than other forms of water heating, some manufacturers are now selling geothermal heat pumps that heat water separately, thereby providing hot water year-round.

Geothermal heat pumps, like all heat pumps, produce slightly warmer air than fossil fuel furnaces. Geothermal heat pumps generally produce hot air between 35 and 39°C (95 and 103°F), as opposed to conventional heat pumps, which produce hot air between 32 and 35°C (90 and 97°F). Geothermal heat pumps require more open ductwork for air flow than fossil fuel furnaces, which can be a problem when converting older houses to geothermal heat.

Geothermal Power Plants

One very promising use of geothermal power is the generation of electricity. Areas with hot geothermal reservoirs can use this heat and steam to create electricity without having to spend money for fuel and without polluting the atmosphere or ground.

Geothermal power plants are similar to other steam turbine thermal power stations in that heat from a fuel source (in the case of geothermal energy, from the core of the Earth) is used to heat water or another working fluid. The working fluid is then used to turn a turbine of a generator, thereby producing electricity.

Geothermal power plants are usually built with modular designs, which makes them very flexible. It is easy to start with a small plant and then add additional units if the demand for electricity increases. Geothermal plants can also use some of their water, either freshly pumped or after being used for electricity, for other direct purposes, such as heating or aquaculture.

However, not every location can use geothermal power. Geothermal power plants must be located near a geothermal reservoir that has water of at least 121°C (250°F) and preferably 150°C (300°F). Not all reservoirs have water this hot. An ideal geothermal reservoir is hot with low mineral content, has shallow aquifers nearby to make it easy to re-inject used water, is on private land in order to make it easier to get permits, is near existing electrical transmission lines, and has a supply of cooler water for cooling. It also needs a high enough volume of water to keep flowing steadily.

In terms of the operation of a geothermal power plant, all types of geothermal power plants use geothermal steam to turn a turbine. The turbine is attached to a generator that creates the electricity. The electricity is then fed into a grid, which is attached to individual users. There are three main types of geothermal power plant: binary, dry steam, and flashed steam. There are also hybrid power plants that combine geothermal energy with other energy sources. The type of plant built in a given area depends on what sort of geothermal resource is available, either steam or liquid and either high or low temperature.

Binary Power Plants

In these binary cycle plants, the main difference is that the water or steam from below the earth never comes in direct contact with the turbines. Instead, water from geothermal reservoirs is pumped through a heat exchanger where it heats a second liquid which boils at a lower temperature than water. This second liquid is heated into steam, which powers the turbines that drives a generator. The hot water from the earth is recycled into the earth through the injection well, and the second liquid is recycled through the turbine and back into the heat exchanger where it can be used again.

Thus, binary power plants use a two-step process to extract power from geothermal water that is not quite hot enough to spin a turbine by itself. The hot water is pumped up through the ground and passed through a heat exchanger that contains a fluid with a much lower boiling point than water. The heat from the geothermal water causes this “binary” fluid to flash into vapor. That vapor spins the turbine, which powers the generator. The geothermal water is injected back into the reservoir. The binary fluid stays inside the tank, where it is used over and over again. Nothing is released into the atmosphere.

Many areas have geothermal reservoirs with water that is below 205°C (400°F). Moderate-temperature geothermal water is much more common than high-temperature water.

Closed Loop Power Plant

Closed loop horizontal power plant systems are the most cost-effective for residential areas. For larger commercial buildings, closed loop vertical systems are more often used. These can sometimes go down 400 feet deep.

In a closed loop system, a water/antifreeze mixture circulates through a loop of pipes underground (or beneath a body of water) and into a building. In the winter (as shown above), the temperatures underground are warmer than the air, so the fluid pumping in is warmer. Then the electric compressors and heat exchangers transfer the heat through ducts in the building. In the summer, the pipes draw heat away from the building and it is absorbed into the earth or water.

Dry Steam Power Plants

Dry steam power plants use the steam that comes up from a geothermal reservoir to power turbines that power generators. Dry steam plants are the most common types of geothermal power plants, accounting for about half of the installed geothermal plants. They work by piping hot steam from underground reservoirs directly into turbines from geothermal reservoirs, which power the generators to provide electricity. After powering the turbines, the steam condenses into water and is piped back into the earth via the injection well.

Flash Steam Power Plants

Flash steam power plants are the most common type of geothermal power plant. This type of power plant differs from the dry steam power plant because hot water, rather than steam, is pumped directly to the surface. The hot water from below the earth into a flash tank on the surface and is at a high pressure.

The fluid is pumped up at high pressure and then sprayed into a tank that is at lower pressure than the water. This causes the geothermal water to “flash,” or turn into steam instantly. The steam spins a turbine, which powers a generator. Fluid left in the first tank is then pumped into another tank to be flashed again. After the water has been used, it is injected back into the reservoir to regain its heat.

Hybrid Power Plants

Some areas do not have enough geothermal energy to run a full power plant. These places can be ideal sites for hybrid power plants that combine different types of power generation. They can combine different types of geothermal energy generation or combine geothermal energy with other energy sources, even fossil fuels.

Open Loop Power Plants

In open loop power plant systems, the water is taken directly from a water source and into the heat pump where it then can either be recycled back into the same source or pumped into another water source (without polluting). The only difference with the water going in and out is a slight change in temperature. Although these systems can be cheaper, they also require a steady flow of water capable of powering your home.

Geothermal Sources

Geothermal sources are categorized into various types which are (i) hydrothermal reservoirs, (ii) geopressurized zones, (iii) hot dry rock, (iv) normal geothermal gradient, and (v) magma.

Hydrothermal Reservoirs

Groundwater can seep down along faults in the crust of the Earth and become heated through contact with hot rocks below. Sometimes, this hot water accumulates in an interconnected system of fractures and becomes a hydrothermal reservoir. The water might remain underground or might rise by convection through fractures to the surface, producing geysers and hot springs.

Hydrothermal reservoirs are the only geothermal sources that have been used for commercial energy production. Because of the high pressure deep below Earth's surface, the water in these sources can become heated well above the usual boiling temperature of 100°C (212°F). As the superheated water makes its way to the surface, either by convection or because a geothermal well has been drilled, some or all of the water will vaporize to become steam because of the lower pressures encountered. The most desirable geothermal sources have high temperatures – above 300°C (570°F) – and all of the water vaporizes to produce dry steam (containing no liquid water), which can be used directly in steam-electric turbines.

Wet steam reservoirs are much more common than the simple dry type. Again, the field is full of hot water, under such high pressure that it cannot boil. When a lower-pressure escape route is provided by drilling, some of the water suddenly evaporates (flashes) to steam, and it is a steam-water mixture that reaches the surface. The steam can be used to drive a turbine. The hot water also can be used to drive a second turbine in a binary cycle. Many geothermal reservoirs contain hot water at a temperature too low for electricity generation. However, the water can be used to

heat buildings such as homes, greenhouses, and fish hatcheries. This heating can be either direct or through the use of heat pumps.

Geopressurized Zones

Geopressurized zones are regions where water from an ancient ocean or lake is trapped in place by impermeable layers of rock. The water is heated to temperatures between 100°C (212°F) and 200°C (390°C) by the normal flow of heat from Earth's core, and because of the overlying rock, the water is held under high pressure. Thus, energy is contained in the water because of both the temperature and the pressure, and can be used to generate electricity. Many geopressurized zones also contain additional energy in the form of methane from the decay of organic material that once lived in the water. The U.S. Geological Survey has estimated that approximately one-third of the energy from geopressurized zones in the United States is available as methane.

Hot Dry Rock

In many regions of the world, hot rocks lie near surface of the Earth, but there is little surrounding water. Attempts have been made to fracture such rocks and then pump water into them to extract the thermal energy, but the technical difficulties in fracturing the rocks have proven to be much more troublesome than anticipated, and there has been a problem with water losses. Consequently, progress in extracting energy from hot, dry rocks has been slow. However, experiments are ongoing in the United States, Japan, and Europe because the amount of energy available from hot, dry rocks is much greater than that from hydrothermal resources.

Normal Geothermal Gradient

In principle, the normal geothermal gradient produces a useful temperature difference anywhere on the globe. If a hole is drilled to a depth of 6 kilometers (which is feasible), a temperature difference of approximately 180°C (325°F) is available, but no technology has been developed to take advantage of this resource. At this depth, water is unlikely, and the problems of extracting the energy are similar to the difficulties encountered with hot, dry rocks near the surface.

Magma

Magma is subterranean molten rock, and although the potential thermal resource represented by magma pools and volcanoes is extremely large, it also presents an immense technological challenge. The high temperatures produce obvious problems with melting and deformation of equipment. The most promising candidates for heat extraction from magma are young volcanic calderas (less than a few million years old) that have magma relatively close to the surface. The hope is that heat can be extracted in this area by drilling a well down to the magma level and pumping water into the well to solidify the magma at the bottom of the well. Then, more water could be pumped into the well, become heated by contact with the solidified magma, and then returned to the surface to generate steam for electricity production.

Giant Reed Grass

Giant reed grass (Spanish cane, wild cane or giant cane, *Arundo donax*) is a wild plant growing in southern Europe regions. Although giant reed grass grows best in a warm climate, certain genotypes can be adapted to cooler climates and can be grown in countries like Germany or the United Kingdom.

Giant reed grass is a perennial that grows in dense clumps, 5 to 20 feet tall. The leaves can be 1 to 2 feet long and from 1 to 2 inches wide at the base and appear alternate on the stem and point straight out. Stems are 1/2 to 1+ inches in diameter and are hollow, resembling bamboo. The roots are tough and fibrous and, along with extensive rhizomes, form knotty, spreading mats that penetrate deep into the soil. The flower heads are borne in a large (up to feet) plume-like terminal panicles. Seed production is low, and those that do form are considered sterile. In nature, giant reed is primarily vegetatively propagated by rhizomes or viable nodes of mature cane.

Giant Reed is one of the most productive crops as its yield reaches more than 12 tons per acre of dry matter as well as one of the most cost-effective energy crops because it is perennial with low annual inputs after establishment of the crop. The annual input consists of harvesting, irrigation, and/or fertilization costs. Giant reed is one of the largest grass species that can be grown in cool temperatures, and it can grow up to 5 meters tall and 3.5 cm in diameter. Giant Reed is usually harvested either in autumn or in a late winter. Though harvesting in late winter can result in losses of the crop yield (leaves and tops are usually lost). Depending on its use, it is either harvested each year or every second year.

Processing of giant reed grass into biofuel may involve gasification and subsequent conversion to synthetic biofuel or conversion into cellulose-ethanol by sequential treatments involving pretreatment, saccharification, and fermentation.

Girbotol Process

The Girbotol process is a continuous, regenerative process to separate hydrogen sulfide, carbon dioxide, and other acid impurities from natural gas, refinery gas, etc., using mono-, di-, or triethanolamine as the reagent.

The process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower called an absorber through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

See also: Gas Cleaning, Gas Cleaning – Chemisorption, Gas Processing.

Girdler Process

The Girdler process is an amine (olamine) washing of natural gas to remove acid gases and involves chemical reaction of the amine with any acid gases with the liberation of an appreciable amount of heat, and it is necessary to compensate for the absorption of heat. Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) have been used in commercial applications.

Amine washing of gas emissions involves chemical reaction of the amine with any acid gases with the liberation of an appreciable amount of heat, and it is necessary to compensate for the absorption of heat. Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) have been used in commercial applications.

The chemistry can be represented by simple equations for low partial pressures of the acid gases:

At high acid gas partial pressure, the reactions will lead to the formation of other products:

The reaction is extremely fast, the absorption of hydrogen sulfide being limited only by mass transfer; this is not so for carbon dioxide.

Regeneration of the solution leads to near complete desorption of carbon dioxide and hydrogen sulfide. A comparison between monoethanolamine, diethanolamine, and diisopropanolamine shows that monoethanolamine is the cheapest of the three but shows the highest heat of reaction and corrosion; the reverse is true for diisopropanolamine.

One key difference among the various specialty amines is selectivity toward hydrogen sulfide; instead of removing both hydrogen sulfide and carbon dioxide, as generic amines such as MEA and DEA do, some products readily remove hydrogen sulfide to specifications, but allow controlled amounts of carbon dioxide to slip through. When the methyl diethanolamine process was developed in the mid-1970s, it was principally destined for the sweetening of gases which did not require complete carbon dioxide removal, or required the removal of only a controlled part of the carbon dioxide. The selectivity of methyl diethanolamine based products can lead to more energy savings. For example, allowing carbon dioxide to remain in the treated gas reduces the amount of acid gas in the amine that needs to be regenerated, thus reducing the amount of energy required.

A series of chemical activators used with methyl diethanolamine offers the most cost-effective answer to complete or controlled acid gas removal from sour to very sour natural gases. However, there are limitations of even the most advanced activated methyl diethanolamine only-based gas treatment technologies in handling very highly acid gas-loaded natural or associated oil field gases, especially for bulk acid gas removal when the acid gases are destined for cycling and/or disposal by re-injection. The activated methyl diethanolamine process is probably the most cost-effective solution to meet the widest range of applications from complete carbon dioxide removal to bulk hydrogen sulfide and/or carbon dioxide removal even for acid gas re-injection projects.

The general process flow diagram for an amine sweetening plant varies little, regardless of the aqueous amine solution used as the sweetening agent. The sour gas containing hydrogen sulfide and/or carbon dioxide will nearly always enter the plant through an inlet separator (scrubber) to remove any free liquids and/or entrained solids. The sour gas then enters the bottom of the absorber column and flows upward through the absorber in intimate counter-current contact with the aqueous amine solution, where the amine absorbs acid gas constituents from the gas stream. Sweetened gas leaving the top of the absorber passes through an outlet separator and then flows to a dehydration unit (and compression unit, if necessary) before being considered ready for sale.

In many units, the rich amine solution is sent from the bottom of the absorber to a flash tank to recover hydrocarbon derivatives that may have dissolved or condensed in the amine solution in the absorber. The rich solvent is then preheated before entering the top of the stripper column. The amine-amine heat exchanger serves as heat conservation device and lowers total heat requirements for the process. A part of the absorbed acid gases will be flashed from the heated rich solution on the top tray of the stripper. The remainder of the rich solution flows downward through the stripper in countercurrent contact with vapor generated in the reboiler. The reboiler vapor (primarily steam) strips the acid gases from the rich solution. The acid gases and the steam leave the top of the stripper and pass overhead through a condenser, where the major portion of the steam is condensed and cooled. The acid gases are separated in the separator and sent to the flare or to processing. The condensed steam is returned to the top of the stripper as reflux.

Lean amine solution from the bottom of the stripper column is pumped through an amine-amine heat exchanger and then through a cooler before being introduced to the top of the absorber column. The amine cooler serves to lower the lean amine temperature to the 100°F range. Higher temperatures of the lean amine solution will result in excessive amine losses through vaporization and also lower acid gas carrying capacity in the solution because of temperature effects.

Diethanolamine (DEA) has a higher boiling temperature than monoethanolamine, requiring other methods of reclaiming such as vacuum distillation in order to prevent thermal degradation of the amine. Moreover, diethanolamine has a slow degradation rate. Consequently, in most cases, it is not practical, economical, or necessary to reclaim DEA solutions. Solution purification is maintained by mechanical and carbon filtration, and by caustic or soda ash addition to the system to neutralize the heat-stable amine salts.

Moisture may be removed from hydrocarbon gases at the same time as hydrogen sulfide is removed. Moisture removal is necessary to prevent harm to anhydrous catalysts and to prevent the formation of hydrocarbon hydrates (such as the propane hydrate, $C_3H_8 \cdot 18H_2O$) at low temperatures. A widely used dehydration and desulfurization process is the glycol/amine process, in which the treatment solution is a mixture of ethanolamine and a large amount

of glycol. The mixture is circulated through an absorber and a reactivator in the same way as ethanolamine is circulated in the Girbotol process. The glycol absorbs moisture from the hydrocarbon gas passing up the absorber; the ethanolamine absorbs hydrogen sulfide and carbon dioxide. The treated gas leaves the top of the absorber; the spent ethanolamine glycol mixture enters the reactivator tower, where heat drives off the absorbed acid gases and water.

The processes using ethanolamine and potassium phosphate are now widely used. The ethanolamine process, known as the Girbotol process, removes acid gases (hydrogen sulfide and carbon dioxide) from liquid hydrocarbon derivatives as well as from natural and from refinery gases. The Girbotol treatment solution is an aqueous solution of ethanolamine, which is an organic alkali that has the reversible property of reacting with hydrogen sulfide under cool conditions and releasing hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower called an absorber through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

Global Climate Change

The environment is in a state of continual change, and not only as a result of modern activities. In fact, ever since life first appeared, the atmosphere has been influenced by the metabolic processes of living organisms. Of which humans have probably caused the greatest changes even though the human tenure on the Earth has been the shortest relative to the terms of other (floral and faunal) species.

Global climate change (often referred to as global warming or global environmental change) is an emotional environmental issue that deals with the potential for global climate change due to increased levels of atmospheric greenhouse gases.

There are many anthropogenic activities which emit a variety of atmospheric contaminants including sulfur dioxide, particulate matter, photochemically reactive hydrocarbon derivatives, chlorofluorocarbon derivatives, and chemicals (such as those that contain toxic heavy metals). These activities include the use (combustion) of fossil fuels which can introduce carbon dioxide, carbon monoxide, sulfur dioxide, nitrogen oxides, hydrocarbon derivatives (including methane), particulate soot, polynuclear aromatic hydrocarbon derivatives, and fly ash into the atmosphere.

Global warming is the increase in the average temperature of the near-surface air and oceans of the Earth since the mid-20th century and its projected continuation. It has been concluded that increasing greenhouse gas concentrations resulting from human activity such as fossil fuel burning and deforestation are responsible for the observed temperature increase since the middle of the 20th century. However, natural phenomena such as solar variation, volcanoes, and the existence of an interglacial period (inter-ice-age period when the Earth will warm) produce most of the warming. These basic facts are often omitted by the global warming proponents, while the opponents deny any contribution from anthropogenic activities. Climate model projections are often based on the fallacy of either view point as well as the failure to recognize the contributions from all sources.

The most commonly cited indication of global warming is the trend in globally averaged temperature near the surface of the Earth which, expressed as a linear trend, show alarming increases in temperature, even though some recent winters have been reminiscent of an ice age.

The issues remain emotional and political, and the mis-use of data and statistics has hurt both proponents and opponents of the theory.

Glycol-Amine Gas Treating

Glycol-amine treating is a continuous, regenerative process to simultaneously dehydrate and remove acid gases from natural gas or refinery gas. The primary process for sweetening sour natural gas is quite similar to the processes of

glycol dehydration and natural gas liquids absorption. In this case, however, amine solutions are used to remove the hydrogen sulfide. This process is known simply as the amine process (olamine process) or alternatively as the Girdler process, and is used in the majority of gas sweetening operations.

In the process, the sour gas is run through a tower, which contains the amine solution. This solution has an affinity for sulfur, and absorbs it much like glycol absorbing water. There are two principle amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from natural gas as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status. Like the process for natural gas liquids, extraction and glycol dehydration, the amine solution used can be regenerated (that is, the absorbed sulfur is removed), allowing it to be reused to treat more sour gas.

Although most sour gas sweetening involves the amine absorption process, it is also possible to use solid desiccants like iron sponges to remove the sulfide and carbon dioxide.

See also Gas Cleaning, Gas Processing, Glycol-Based Processes.

Glycol-Based Processes

Absorption dehydration involves the use of a liquid desiccant to remove water vapor from the gas. Although many liquids possess the ability to absorb water from gas, the liquid that is most desirable to use for commercial dehydration purposes should possess the following properties: (i) high absorption efficiency, (ii) relatively easy and economic regeneration, (iii) non-corrosive and non-toxic, (iv) no operational problems when used in high concentrations, and (v) no interaction with the hydrocarbon portion of the gas, and no contamination by acid gases.

Glycols are the most widely used absorption liquids as they approximate the properties that meet the commercial application criteria. The glycol derivatives, particularly ethylene glycol (EG), diethylene glycol (DEG), triethylene glycol (TEG), and tetraethylene glycol are the most appropriate for satisfying these criteria to varying degrees. Water and the glycols show complete mutual solubility in the liquid phase due to hydrogen-oxygen bonds, and their water vapor pressures are very low. A frequently used process is the triethylene glycol (TEG) process. In those situations where inhibition is not feasible or practical, dehydration must be used. Both liquid and solid desiccants may be used, but economics frequently favor liquid desiccant dehydration when it will meet the required dehydration specification.

In the process, wet natural gas first enters an inlet separator to remove all liquid hydrocarbon derivatives from the gas stream. Then, the gas flows to an absorber (contactor) where it is contacted countercurrently and dried by the lean triethylene glycol. However, the triethylene glycol also absorbs volatile organic compounds (VOCs) that vaporize with the water in the reboiler. Dry natural gas exiting the absorber passes through a gas/glycol heat exchanger, and then into the sales line. The wet (rich) glycol exiting the absorber flows through a coil in the accumulator where it is preheated by hot lean glycol. After the glycol-glycol heat exchanger, the rich glycol enters the stripping column and flows down the packed bed section into the reboiler. Steam generated in the reboiler strips absorbed water and volatile organic compounds out of the glycol as it rises up the packed bed. The water vapor and desorbed natural gas are vented from the top of the stripper. The hot regenerated lean glycol flows out of the reboiler into the accumulator (surge tank) where it is cooled via cross exchange with returning rich glycol; it is pumped to a glycol/gas heat exchanger and back to the top of the absorber.

Glycol derivatives are typically used for applications where dew point depressions of the order of 15 to 49°C (59 to 120°F) are required. Diethylene glycol (DEG), triethylene glycol (TEG), and tetraethylene glycol (TREG) are used as liquid desiccants, but TEG is the most common for natural gas dehydration.

In the triethylene glycol process, wet gas first enters an inlet separator to remove all liquid hydrocarbon derivatives from the gas stream after which the gas flows to an absorber (contactor) where it is contacted countercurrently and dried by the lean triethylene glycol. The triethylene glycol also absorbs volatile organic compounds (VOCs) that vaporize with the water in the reboiler. The dry natural gas exiting the absorber passes through a gas/glycol heat exchanger and then into the sales line. The wet or rich triethylene glycol exiting the absorber flows through a coil in the accumulator where it is preheated by hot lean glycol. After the glycol-glycol heat exchanger, the rich glycol enters the stripping column and flows down the packed bed section into the reboiler. Steam generated in the reboiler strips absorbed water and volatile organic compounds out of the glycol as it rises up the packed bed, and the water vapor

and desorbed natural gas are vented from the top of the stripper. The hot regenerated lean triethylene glycol flows out of the reboiler into the accumulator (surge tank) where it is cooled via cross exchange with returning rich glycol; it is pumped to a glycol/gas heat exchanger and back to the top of the absorber.

Generally, the contact between a wet gas and glycol can be made in any gas-liquid contact device and is predominantly an absorption/stripping type process, similar to the oil absorption process. The wet gas is dehydrated in the absorber, and the stripping column regenerates the water-free triethylene glycol. The glycol stream should be recharged constantly because some triethylene glycol may react and form higher-molecular-weight products which should be removed by the filter shown or by distillation of a slip stream.

A distinct difference between the chemical-based (e.g., glycol absorption) and the non-chemical-based (e.g., adsorption) dehydration techniques is that the chemical-based techniques will saturate the gas with chemicals at operational conditions. Both techniques can in principle remove almost all the water from the gas, but the phase behavior of the natural gas leaving the processes will be different. Even though chemicals used for absorption in general will have low vapor pressure and relatively small amounts will condense per cubic meter gas, the effect of condensation has to be considered in design of pipelines and process equipment.

The glycol derivative has a chemical affinity for water and removes water from the gas stream. In this process, a liquid desiccant dehydrator serves to absorb water vapor from the gas stream. Essentially, glycol dehydration involves using a glycol solution, usually either diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the wet gas stream in a *contactor*. The glycol solution will absorb water from the wet gas, and once absorbed, the glycol particles become heavier and sink to the bottom of the contactor where they are removed. The natural gas, having been stripped of most of its water content, is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the natural gas, is put through a specialized boiler designed to vaporize only the water out of the solution. The boiling point differential between water (100°C, 212°F) and glycol (204°C, 400°F) makes it relatively easy to remove water from the glycol solution, allowing it to be reused in the dehydration process.

As well as absorbing water from the wet gas stream, the glycol solution occasionally carries with it small amounts of methane and other compounds found in the wet gas. In the past, this methane was simply vented out of the boiler. In addition to losing a portion of the natural gas that was extracted, this venting contributes to air pollution and the greenhouse effect. In order to decrease the amount of methane and other compounds that are lost, flash tank separator-condensers work to remove these compounds before the glycol solution reaches the boiler. Essentially, a flash tank separator consists of a device that reduces the pressure of the glycol solution stream, allowing the methane and other hydrocarbon derivatives to vaporize (*flash*). The glycol solution then travels to the boiler, which may also be fitted with air- or water-cooled condensers, which serve to capture any remaining organic compounds that may remain in the glycol solution. The regeneration (stripping) of the glycol is limited by temperature: diethylene glycol and triethylene glycol decompose at or before their respective boiling points. Such techniques as stripping of hot triethylene glycol with dry gas (e.g., higher-molecular-weight hydrocarbon vapors, the Drizo process) or vacuum distillation are recommended.

See also: Gas Cleaning.

Glycol Degradation

Glycol degradation is caused primarily by either oxidation or thermal degradation. Glycol readily oxidizes to form corrosive acids. Oxygen can enter the system with incoming gas, from unprotected storage tanks or sumps, and through packing glands. Although oxidation inhibitors (such as a 50-50 blend of monoethanolamine (MEA) and 33% hydrazine solution) can be used to minimize corrosion, a better approach to controlling oxidation is blanketing the glycol with natural gas, which can be applied to the headspace in storage tanks and any other area where glycol may contact oxygen. Thermal degradation of the glycol results from the following conditions: high reboiler temperature, high heat flux rate, and localized overheating. The reboiler temperature should always be kept below 400°F to prevent degradation, and a good fire tube design should inherently prevent a high heat flux rate. Localized overheating can be caused by deposits of salts or hydrocarbon derivatives. In addition, thermal degradation of the glycol produces acidic degradation products that lower the pH and increase the rate of degradation, creating a destructive cycle.

Glycol Dehydration

Natural gas from the well is usually saturated with water which in the presence of methane at low temperature can form hydrates, which are solids which will block pipes and valves and stop the operation of the plant.

Among the different gas drying processes, absorption is the most common technique, where the water vapor in the gas stream becomes dissolved in a liquid solvent stream. Glycols are the most widely used absorption liquids as they approximate the properties that meet the commercial application criteria. Several glycols have been found suitable for commercial application. The commonly available glycols and their uses are described as follows:

1. Monoethylene glycol (MEG); high vapor equilibrium with gas so tend to lose to gas phase in contactor. Use as hydrate inhibitor where it can be recovered from gas by separation at temperatures below 50°F.
2. Diethylene glycol (DEG); high vapor pressure leads to high losses in contactor. Low decomposition temperature requires low reconcentrator temperature (157 to 170°C, 315 to 340°F) and thus cannot get pure enough for most applications.
3. Triethylene glycol (TEG); most common. Reconcentrate at 170 to 205°C (340 to 400°F) for high purity. At contactor temperatures in excess of 50°C (120°F) tends to have high vapor losses to gas. Dew point depressions up to 67°C (150°F) are possible with stripping gas.
4. Tetraethylene glycol (TREG); more expensive than TEG but less loss at high gas contact temperatures. Reconcentrate at 400 to 430 °F.

Triethylene glycol is by far the most common liquid desiccant used in natural gas dehydration. It exhibits most of the desirable criteria of commercial suitability:

1. Triethylene glycol is more easily regenerated to a concentration of 98-99 % in an atmospheric stripper because of its high boiling point and decomposition temperature.
2. Triethylene glycol has an initial theoretical decomposition temperature of 207°C (404°F), while that of diethylene glycol is only 164°C (328°F).
3. Vaporization losses are lower than monoethylene glycol or diethylene glycol.
4. Triethylene glycol is not too viscous above 21°C (70°F).

Ethylene glycol is injected into the gas upstream of the plant, where it combines with any free water. After the water is separated from the gas and natural gas liquids, the water is put through a reboiler where the glycol boils off and is recycled for re-use.

The glycol plant is often the least stable component of a gas system and requires the most operator attention. A glycol contacting column (with the gas flowing up through glycol coming down) can also be used to provide a more efficient process and is usually a better option if NGLs are to be transported with the gas in the pipeline in two-phase flow.

Some systems use methanol for drying the gas. The methanol is injected upstream of the cooling process where it combines with the water. The methanol is later recovered from the liquid water/methanol mixture by stripping with a slip stream of the feed gas in a stripper column. Pure water is recovered from the bottom of the column, and the methanol saturated stream from the top is recirculated back into the main gas stream.

In a typical triethylene glycol dehydration process, water-saturated gas enters near the bottom of the contactor tower and flows upwards through the internal trays/packing. Lean glycol enters the contactor tower near the top and cascades down through the contactor making contact with the up-flowing gas stream. The countercurrent flow path of the glycol and the high contact surface area adsorbs water into the glycol from the gas stream. Dehydrated gas flows out of the top of the contactor, while the rich glycol flows out of the bottom of the contactor and to the glycol regeneration section.

The glycol regeneration process typically involves passing the rich glycol through the still column to gain some heat before entering the flash drum. The glycol is then passed through particle filters to remove particulates and activated carbon filters to remove any dissolved hydrocarbon and/or chemical compounds. The rich glycol is heated in a cross exchanger to preheat the feed to the still column where the glycol present in the water vapor leaving the reboiler is recovered.

Depending on the application, it may be necessary to increase the lean glycol concentration by using stripping gas, or running the reboiler/still column under a slight vacuum. Lean glycol (typically >99% w/w purity) is then cooled and pumped back to the top of the contactor tower to repeat the process.

(See also: Gas Cleaning, Gas Processing.)

Gobar Gas

Gobar gas is biogas generated out of cow dung. In India, Gobar gas is generated at the countless number of micro plants (an estimated more than 2 million) attached to households. The Gobar gas plant is basically an airtight circular pit made of concrete with a pipe connection.

Gobar gas production is an anaerobic process and is carried out in an airtight, closed cylindrical concrete tank (digester). The tank has a concrete inlet basin on one side for feeding fresh cattle dung (gobar). There is a concrete outlet on the outer side for removing the digested sludge. The top of the tank serves as the gas tank. It has an outlet pipe for the gobar gas.

In the process, fresh cattle dung is mixed with equal amount of water, and fed daily into the digester tank through the inlet and allowed to remain there. Gobar gas collects in the space above the slurry in the main tank. It is conducted through the outlet pipe and used for domestic purposes. The digested sludge (digested biomass) is automatically removed from the tank through and is an excellent fertilizer.

The degree of digestion of the gobar from the beginning to the end is determined by the ambient temperature. If the temperature is not high enough, then all the gobar is not digested and so there is less gas and the output slurry is not as rich in nitrogen and so is not such a good fertilizer. Anyway, that is the price in these cold climates.

See also: Anaerobic Digestion, Biogas, Digesters.

Grain Crops

Grain crops include corn, wheat, rice, barley, and other cereals. The seeds of these plants are typified by their high starch content that can be hydrolyzed to fermentable sugars for ethanol production. The sugar crops, including sugar cane, beet, and sweet sorghum, are preferable to the starch crops to the extent that sucrose is more readily hydrolyzed to fermentable sugars. However, sugar cane production is restricted to warm climates, and requires both high-quality land and irrigation.

Sugar beets produce only 40% as much fermentable sugar as does sugar cane per unit growing area, and reportedly have a higher value as cattle feed than as an energy feedstock. Sweet sorghum is currently a minor crop in the United States, but has considerable advantages over sugar cane as an energy crop. It can grow in a variety of soils and climatic conditions, and its production costs have been estimated to be just over half those for sugar cane.

A most important factor that arises in considering the use of cropland for energy is the competition with the food market. There is no assurance that cropland will in the future be available in the United States for energy uses, and the cultivation of specific energy crops may have to be limited to avoid inflation of food prices.

Crop residues do not have the high starch or sugar content of the crop itself, but are essentially lignocellulosic materials. As in the case of grasses, crop residues are probably more suited to gasification or direct combustion. Processes for the conversion of cellulosic biomass to ethanol are, however, being investigated and may prove viable.

See also: Crops Residue, Crops.

Grasses

Grasses are usually herbaceous plants with narrow leaves growing from the base. They include the true grasses of the Poaceae (or Gramineae) family, as well as the sedges (Cyperaceae) and the rushes (Juncaceae).

The true grasses include cereals, bamboo, and the grasses of lawns (turf) and grassland. Sedges include many wild marsh and grassland plants, and some cultivated ones such as water chestnut (*Eleocharis dulcis*) and papyrus sedge (*Cyperus papyrus*).

Most of the interest in grass biomass tends to focus on economics, but there is a list of traits that should be considered and valued when evaluating a potential solid biomass energy source. These traits are beneficial to society in general, or impact the suitability of biomass for a farm operation.

See also: Reed Canary Grass, Sorghum.

Grassland Pasture and Range

All open land used primarily for pasture and grazing, including shrub and brush land types of pasture; grazing land with sagebrush and scattered mesquite; and all tame and native grasses, legumes, and other forage used for pasture or grazing; because of the diversity in vegetative composition, grassland pasture and range are not always clearly distinguishable from other types of pasture and range; at one extreme, permanent grassland may merge with cropland pasture, or grassland may often be found in transitional areas with forested grazing land.

Grease Car

A grease car is a diesel-powered automobile rigged postproduction to run on used vegetable oil.

In an effort to reduce dependency on crude oil-based fuels, there is an interest in installing conversion kits which allow diesel engines to burn waste vegetable oil along with standard diesel or biodiesel fuel.

A grease car uses filtered vegetable oil, often obtained at little to no cost from local restaurants, to power a slightly modified diesel engine. The primary modifications made to a grease car are a new storage tank for the vegetable oil, additional fuel filters, and a heater to bring the oil up to operating temperature.

A grease car gets approximately the same mileage as a regular diesel car, and the emission levels are a marked improvement over other types of vehicles, making it a phenomenal tool for reducing pollution. Greenhouse gas emissions can drop anywhere from 78 to 87% overall when you convert a diesel car to a grease car. While they still emit nitrogen oxides and carbon monoxide, grease cars are carbon-neutral.

A grease car may also require standard diesel fuel during the start-up process since the vegetable oil may not readily ignite at lower air temperatures until warmed by a heater unit.

One difficulty grease car owners face is a regular supply of suitable vegetable oil, and the owner of such a vehicle should first negotiate with local restaurants and other food establishments to pick up their waste oil for free. In addition, the oil must also be filtered, which means investing in a commercial filtering system or creating one from scratch.

See also: Biodiesel, Vegetable Oil.

Grease Trap

A grease trap consists of a small tank or chamber which slows the speed of product or effluent flow. In the grease trap, fats, oils, and grease float to the top of the water phase and form a layer of scum (sometimes referred to as sludge) that is contained within the tank. This can then be removed and disposed of as chemical waste or be recognized as a potentially useful product. Relatively clean water exits from the grease trap for disposal.

See also: Chemical Waste, Sludge, water.

Greenhouse Effect

The greenhouse effect is the rise in temperature that the Earth experiences because certain gases in the atmosphere (for example: water vapor, carbon dioxide, nitrous oxide, and methane) trap energy from the sun.

The amount of heat energy added to the atmosphere by the greenhouse effect is controlled by the concentration of greenhouse gases in the atmosphere of the Earth. All of the major greenhouse gases have increased in concentration since the beginning of the Industrial Revolution (approximately 1700 AD). As a result of these higher concentrations, scientists

predict that the greenhouse effect will be enhanced and the climate of the Earth will become warmer. Predicting the amount of warming is accomplished by computer modeling. Computer models suggest that a doubling of the concentration of the main greenhouse gas, carbon dioxide, may raise the average global temperature between 1 and 3° Celsius.

However, the numeric equations of computer models do not accurately simulate the effects of a number of possible negative feedbacks. For example, many of the models cannot properly simulate the negative effects that increased cloud cover would have on the radiation balance of a warmer Earth. Increasing the temperature of the Earth would cause the oceans to evaporate greater amounts of water, causing the atmosphere to become cloudier. These extra clouds would then reflect a greater proportion of the energy of the Sun back into space reducing the amount of solar radiation absorbed by the atmosphere and the surface of the Earth. With less solar energy being absorbed at the surface, the effects of an enhanced greenhouse effect may be counteracted.

A number of gases are involved in the human-caused enhancement of the greenhouse effect and include carbon dioxide (CO_2); methane (CH_4); nitrous oxide (N_2O); chlorofluorocarbons (CF_xCl_x); and tropospheric ozone (O_3). Of these gases, the single most important gas is carbon dioxide which accounts for approximately 55% of the change in the intensity of the greenhouse effect.

See also: Greenhouse Gases.

Greenhouse Gases

Greenhouse gases are chemical compounds that contribute to the greenhouse effect. When in the atmosphere, a greenhouse gas allows sunlight (solar radiation) to enter the atmosphere where it warms the surface of the Earth and is reradiated back into the atmosphere as longer-wave energy (heat). Greenhouse gases absorb this heat and trap it in the lower atmosphere. The two major greenhouse gases are water vapor and carbon dioxide. Other greenhouse gases include methane, ozone, chlorofluorocarbons, and nitrous oxide.

Some greenhouse gases such as carbon dioxide occur naturally and are emitted to the atmosphere through natural processes and human activities. Other greenhouse gases (e.g., fluorinated gases) are created and emitted solely through human activities. The principal greenhouse gases that enter the atmosphere because of human activities are carbon dioxide, methane, nitrous oxide, and fluorinated gases.

Carbon dioxide enters the atmosphere through the burning of fossil fuels (oil, natural gas, and coal), solid waste, trees, and wood products, and also as a result of other chemical reactions (e.g., manufacture of cement). Carbon dioxide is also removed from the atmosphere when it is absorbed by plants as part of the biological carbon cycle.

Methane is emitted during the production and transport of coal, natural gas, and oil. Methane emissions also result from livestock and other agricultural practices and by the decay of organic waste in municipal solid waste landfills.

Nitrous oxide is emitted during agricultural and industrial activities, as well as during combustion of fossil fuels and solid waste.

Hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride are synthetic, powerful greenhouse gases that are emitted from a variety of industrial processes. Fluorinated gases are sometimes used as substitutes for ozone-depleting substances (i.e., chlorofluorocarbons, hydrochlorofluorocarbons, and halons). These gases are typically emitted in smaller quantities, but because they are potent greenhouse gases, they are sometimes referred to as high global warming potential gases (high GWP gases).

Greenhouse gases vary in their ability to absorb and hold heat in the atmosphere (greenhouse effect). Hydrofluorocarbons and perfluorocarbons are the most heat-absorbent, but there are also wide differences between naturally occurring gases. For example, nitrous oxide absorbs 270 times more heat per molecule than carbon dioxide, and methane absorbs 21 times more heat per molecule than carbon dioxide.

See also: Greenhouse Effect.

Greenhouse Gas Production

Greenhouse gas production associated with lignocellulosic-based feedstocks is anticipated to be much lower than with conventional fuels. The environmental performance depends very much on the specific life cycle of the fuel,

including the country in which the life cycle assessment (LCA) was conducted, the feedstock on which the fuel is based, the vehicle used, the propulsion system, and the overall state of technology.

In general, fuels (and chemicals) made from lignocellulosic materials are characterized by reduced carbon dioxide emissions when compared to similar products derived from crude oil. Most biofuels can reduce greenhouse gas emissions significantly and substituting emissions by utilizing bio-based energy can create an overall negative emission for the fuel.

Fischer-Tropsch (F-T) fuels based on bio-residues are likely to have the lowest possible emissions; this is typical of diesel propulsion systems that have better energy recovery. If energy crops are utilized as a feedstock, the overall emissions rise slightly, because the benefit of residue disposal is lost. Ethanol from residues or from energy crops also have relatively low emissions, particularly compared to conventional fuels including gasoline and diesel fuel.

For ethanol from lignocellulose, there is a potential to reduce greenhouse gas emissions with improved technology. This reflects the close-to-commercial status of the technology and the anticipated improvements that will be seen as this technology improves.

Gross Sample

For analytical purposes, there should be a sampling plan which typically involves three steps which are (i) physically removing the sample from the material – i.e., the target material or target population, (ii) preserving the sample, and (iii) preparing the sample for analysis. Except for in situ sampling, a sample is analyzed after removing it from its target material and because sampling exposes the target material to potential contamination, the sampling device must be inert and clean.

After removing a sample from the target material, there is a possibility (depending upon the chemical properties and the physical properties of the material) that it will undergo a chemical or physical change (as a result of chemical processes, biological processes, or physical processes) before the analysis can be completed. If such a change occurs, the properties of the sample no longer are representative of the target material population. To circumvent such a problem, any sample taken in the field must be preserved (protected) before transporting the samples to the laboratory for analysis. Even when analyzing samples in the field, preservation may still be necessary. After preserving a sample, it may be safely stored for later analysis. The maximum holding time between preservation and analysis depends on the stability of the sample and the effectiveness of sample preservation.

The initial sample taken from the target material is the gross sample, and may be (i) a single increment drawn from the target material or (ii) a composite of several increments. In many cases, the gross sample cannot be analyzed without first reducing the size of the sample and converting the sample into a more readily analyzable form, or improving the homogeneity of the sample. While this is particularly true for solid sample, liquids and gaseous sample may stratify in the storage container and, therefore not be the presentative sample that is desired.

Furthermore, unlike gases and liquids, a solid sample usually needs some processing before analysis because the standard deviation for sampling is a function of the number of particles in the sample, not the combined mass of the particles. For a heterogeneous material consisting of large particles, the gross sample may be too large to analyze. Reducing the average particle size in the sample allows the analysts to collect the same number of particles with a smaller, more manageable mass.

Reducing the particle size is accomplished by a combination of crushing and grinding the gross sample. The resulting particles are then thoroughly mixed and divided into sub-samples of smaller mass. However, this process may not occur in a single step and the sub-samples may require recycling through the crushing and grinding process several times until a final laboratory sample is obtained.

Thus, a gross sample of a feedstock or product is a sample that represents a quantity, or increment, of a larger quantity of the material to be analyzed and is composed of a number of increments on which neither reduction nor division has been performed. More specifically, the samples chosen for analysis are often called sampling increments or sampling units. In summary, the collection of sampling units or increments is called the gross sample. For laboratory analysis, the gross sample is usually reduced in size and homogenized to create the laboratory sample and the method of obtaining a laboratory sample can be represented simply as follows:

Identify/collect the material → collect a gross sample → reduce to a laboratory sample

The goals of the sampling process are: (i) to obtain a sample that is representative of the total material to be analyzed and which is representative (i.e., an unbiased estimate of the whole sample) – this goal can be realized only if all parts of the material to be analyzed have an equal probability of being included in the sample, and (ii) to obtain a variance in the measured analyte concentration that is an unbiased estimate of the material so that valid confidence limits can be found for the mean – this goal can be reached only if every possible sample is equally likely to be drawn. Both goals require obtaining a random sample – a randomization procedure may be used wherein the samples taken from the material are assigned a number, and then a sample to be tested is selected from a table of random numbers.

Ideally, the gross sample is a miniature replica of the entire mass of material to be analyzed. It is the collection of individual sampling units and must be representative of the whole in composition and in particle-size distribution. The size of the gross sample is determined by (i) the uncertainty that can be tolerated between the composition of the gross sample and that of the whole material, (ii) the degree of heterogeneity of the whole, and (iii) for solid material, the level of particle size at which heterogeneity begins. Specifically, the composition of the gross sample and the laboratory sample must closely resemble (in fact, be a replica of) the average composition of the total mass of material to be analyzed.

The mineral matter content of the feedstock (often incorrectly designated as ash content since there is no ash in, for example, raw biomass feedstocks) is the property most often used in evaluating sampling procedures. Environmentally, sulfur content has also been applied in the evaluation of sampling procedures.

Groundwater

Groundwater is a vital resource that plays a crucial role in geochemical processes, such as the formation of secondary minerals. Groundwater is the part of the hydrosphere most vulnerable to damage from chemical wastes and fuels (conventional or unconventional) that are inadvertently spilled on to the surface of the Earth. The nature, quality, and mobility of groundwater are all strongly dependent upon the rock formations in which the water is held.

Groundwater in nature occurs in two different zones: (i) an unsaturated zone, and (ii) a saturated zone. The unsaturated zone occurs immediately below the land surface in most areas and contains both water and air. In the unsaturated zone, flow occurs beneath the land surface and above the groundwater table. The groundwater table forms the boundary between unsaturated subsurface flow (above it) and saturated subsurface flow (below it). In the unsaturated zone, the preferred path of movement of moisture is vertical, by percolation, toward the saturated zone. Water in the saturated zone is the only water under the surface that is available to supply wells and springs and is the only water to which the name groundwater is correctly applied. Recharge of the saturated zone occurs by percolation of water from the land surface through the unsaturated zone. The water table is the level in the saturated zone at which the hydraulic pressure is equal to the atmospheric pressure and is represented by the water table. Below the water table, the hydraulic pressure increases with increasing depth. In the saturated zone, the preferred path of movement of moisture is horizontal, toward aquifer discharge areas.

Although surface water supplies are subject to contamination, groundwater can become almost irreversibly contaminated by the improper land disposal of chemicals and fuels. Once there is penetration into aquatic systems, chemical species are subject to a number of chemical and biochemical processes. These include acid-base, oxidation-reduction, precipitation-dissolution, and hydrolysis reactions, as well as biodegradation.

Under many circumstances, biochemical processes largely determine the fates of chemical species in water. The most important such processes are those mediated by microorganisms. In particular, the oxidation of biodegradable organic wastes in water generally occurs by means of microorganism-mediated biochemical reactions. Bacteria produce organic acids and chelating agents, such as citrate, which have the effect of solubilizing heavy metal ions. Some mobile methylated forms, such as compounds of methylated arsenic and mercury, are produced by bacterial action.

Physically, an important characteristic of such formations is their porosity, which determines the percentage of rock volume available to contain water. A second important physical characteristic is permeability, which describes

the ease of flow of the water through the rock. High permeability is usually associated with high porosity. However, clays tend to have low permeability even when a large percentage of the volume is filled with water.

Most groundwater originates from precipitation in the form of rain or snow. Water from precipitation that is not lost by evaporation, transpiration, or to stream runoff, may infiltrate into the ground. Initial amounts of water from precipitation onto dry soil held very tightly as a film on the surfaces and in the micropores of soil particles. At intermediate levels, the soil particles are covered with films of water, but air is still present in larger voids in the soil. The region in which such water is held is called the unsaturated zone or zone of aeration, and the water present in it is vadose water. At lower depths, in the presence of adequate amounts of water, all voids are filled to produce a zone of saturation, the upper level of which is the water table.

Groundwater is in constant motion from a point of recharge to a point of discharge in accordance with the laws governing flow of fluids in porous media. The law of linear resistance gives the rate at which groundwater in motion loses energy. Further, because of addition and withdrawal from storage, the volume of groundwater in motion changes with distance according to the principle of conservation of mass. In general, this can be expressed through equation of continuity:

$$\text{Mass inflow rate} = \text{mass outflow rate} + \text{change of mass storage with time}$$

The rate of movement of groundwater depends on the type of subsurface rock materials in a given area. Saturated permeable formations like sands, gravel, weathered/fractured, or structurally deformed hard rocks are a favorable medium for groundwater flow. Impermeable formations such as clay minerals, shale, fines, silts, and solid hard rocks do not offer or favor easy groundwater flow.

In areas where groundwater is used faster than it is naturally replenished, groundwater shortage is faced for small periods or continually depending upon the recharge rate. The categorization of areas for groundwater development suggests four categories: (i) safe, (ii) semi critical, (iii) critical, and (iv) over-exploited. The stage is defined as the ratio of the existing groundwater draft to the net annual groundwater availability. The net annual groundwater availability has been defined as the estimated resource minus a certain allowance for the natural groundwater discharge.

In certain areas, groundwater is polluted by natural processes and the groundwater is contaminated with minerals such as like fluoride, arsenic, and nitrate; groundwater can be polluted by industrial effluents, landfills, septic tanks, leaky underground pipelines, and from overuse of fertilizers and pesticides. When groundwater becomes polluted, it will no longer be safe to drink. The majority of the population in India is in the urban areas, and almost everyone who lives in rural areas uses groundwater for drinking water. The largest use for groundwater is to irrigate crops.

See also: Groundwater Aquifer.

Groundwater Aquifer

A groundwater aquifer is an underground layer of a water-bearing permeable rock, a rock fracture, or unconsolidated material such as gravel, sand, or silt from which the water can be extracted by means of a well. The terms related to aquifer are (i) aquitard, which is a bed of low permeability along an aquifer and (ii) aquiclude or aquifuge, which is a solid, impermeable area underlying or overlying an aquifer, the pressure of which could create a confined aquifer.

As a source of sustainable drinking water, a groundwater aquifer normally requires a means of recharging. Most groundwater aquifers are replenished via rivers or rain. This water may seep into the groundwater aquifer as groundwater flow through the soil. Sometimes, an aquifer may fill up during a rainy season, and then gradually dry out during the summer.

The depth at which a groundwater aquifer is found in a particular geographic region usually depends on the level of the water table in the area. The water table refers to the depth under the ground at which the pressure of groundwater is equal to the pressure of the atmosphere, and usually is regarded as the top level of accessible groundwater in a given area. The water table depth changes with time, and there may be a significant difference in the water table depth from season to season, which can affect the depth at which local groundwater aquifers are accessible.

Growing Stock

The forests of the world fulfill many roles such as (i) providing renewable raw materials and energy, (ii) maintaining biodiversity, and (iii) protecting land and water resources. However, they can be damaged by fire, agricultural and urban expansion, and other disturbances.

Forests influence climate change by affecting the amount of carbon dioxide in the atmosphere by removing carbon dioxide from the atmosphere by absorption in the wood, the leaves, and the soil. Because forests can absorb and store carbon over an extended period of time, they are often labeled as carbon sinks. This carbon remains stored in the forest ecosystem but can be released into the atmosphere when forests are burned. Quantifying the substantial roles of forests in absorbing, storing, and releasing carbon is key to understanding the global carbon cycle and hence climate change.

Growing stock is a measure of the volume of stem-wood in an area of forest or wooded land and provides information on existing wood resources but also a basis for estimating the amount of carbon contained. Overall, growing stock has been decreasing slightly with some regional differences: Africa, Asia, and South America show a slight decrease, while Europe as well as North and Central America show a slight increase. The term carbon stock refers to the amount of carbon stored in the forest ecosystems of the world, predominantly in living biomass and soil but to a lesser extent also in dead wood and litter.

Thus, growing stock is a classification of timber inventory that includes live trees of commercial species meeting specified standards of quality or vigor; cull trees are excluded. The term growing stock volume refers to the above-stump volume of living trees measured from the bark up to the treetops. It includes all living trees, the diameter of which at breast height (dbh. – or 4 feet) is over 0 cm. It is the living tree component of the standing volume, which also includes dead trees.

The average annual mortality of growing stock is the average cubic foot volume of sound wood in growing-stock trees that died in one year. This statistic is an average for the years between inventories. Growing stock data provide not only information on existing wood resources but also a basis for estimating the amount of carbon contained.

Guard Bed

A guard bed is a bed of an adsorbent (such as, for example, bauxite) that protects a catalyst bed by adsorbing species detrimental to the catalyst. Catalyst bed fouling is present to some degree in, for example, hydrotreating units. When fouling begins to affect hydrotreater cycle length, it is necessary to employ guard bed catalysts to protect valuable downstream catalyst.

The foulants that cause problems in a hydrotreater come from several different sources. The primary foulants are in the feed, or are generated in the equipment upstream of the hydrotreater or even in the hydrotreater itself. These foulants fall into three different categories which are (i) particulates of widely varying size and composition, (ii) reactive molecules such as olefin derivatives and oxygenate derivatives, and (iii) inorganic chemical poisons such as arsenic, nickel, iron, vanadium, and silicon.

The solution is a graded system of guard bed catalysts to balance the deposition and storage of particulates at different layers in the catalyst bed.

The guard bed can be made up of any suitable adsorbing material, which has (i) high adsorption capacity, insofar as the material is porous and has a high surface area, (ii) high selectivity for the contaminants, (iii) structures stable to chemical or thermal attack, and (iv) regenerability at typical regeneration conditions.

Suitable guard bed materials are dependent upon the material to be removed and include activated charcoal, or a siliceous material including clay, silica, silica gel, silica-alumina, and zeolite. Siliceous material of high adsorption capacity as exhibited by a surface area of 1 to 1,000 m² per gram, preferably 10 to 500 m² per gram is preferable. Another approach entails the use of an adsorbent of slight acidity, a strong acidity being undesirable owing to the difficult regeneration of strongly adsorbed organic bases. The zeolites can be partially ion-exchanged and in the hydrogen form to adjust their acidity.

Guard Bed Reactor

Feedstocks that have relatively high content of metals (>300 ppm) substantially increase catalyst consumption because the metals poison the catalyst, thereby requiring frequent catalyst replacement. The usual desulfurization catalysts are relatively expensive for these consumption rates, but there are catalysts that are relatively inexpensive and can be used in the first reactor to remove a large percentage of the metals. Subsequent reactors downstream of the first reactor would use normal hydrodesulfurization catalysts. Since the catalyst materials are proprietary, it is not possible to identify them here. However, it is understood that such catalysts contain little or no metal promoters, i.e., nickel, cobalt, and molybdenum. Metals removal on the order of 90% has been observed with these materials.

Thus, one method of controlling demetallization is to employ separate smaller guard reactors just ahead of the fixed-bed hydrodesulfurization reactor section. The preheated feed and hydrogen pass through the guard reactors that are filled with an appropriate catalyst for demetallization that is often the same as the catalyst used in the hydrodesulfurization section. The advantage of this system is that it enables replacement of the most contaminated catalyst (guard bed), where pressure drop is highest, without having to replace the entire inventory or shut down the unit. The feedstock is alternated between guard reactors while catalyst in the idle guard reactor is being replaced.

When the expanded-bed design is used, the first reactor could employ a low-cost catalyst (5% of the cost of Co/Mo catalyst) to remove the metals and subsequent reactors can use the more selective hydrodesulfurization catalyst. The demetallization catalyst can be added continuously without taking the reactor out of service, and the spent demetallization catalyst can be loaded to more than 30% vanadium, which makes it a valuable source of vanadium.

Gum

An insoluble tacky semi-solid material formed as a result of the storage instability and/or the thermal instability of fuels from a variety of sources.

Gasoline and diesel fuel are susceptible to formation of insoluble gum upon exposure to atmospheric oxygen. During storage, gum formation is particularly severe in fuels derived from catalytic refining processes. Gum formation in gasoline is the result of oxidation and polymerization of unsaturated components, particularly dienes or highly unsaturated compounds, the resulting product being resinous gums. Similarly, diesel fuels form gums during storage. Some types of gums are soluble in the fuel, and a residue is formed after the fuel has been evaporated. Thus, a buildup of gum can form on the fuel injection system. Moreover, insoluble solid particles can form when stocks containing dissolved gums are blended together. The particles can clog fuel filters and injection systems. When motor fuels are stored for any considerable period, an additive to inhibit oxidative gum formation is incorporated into the fuel.

Gum content is influenced by the age of the fuel and its exposure to oxygen and certain metals such as copper. If the fuel (such as gasoline) is allowed to evaporate, the residue left can form gum and varnish. It is important for the fuel to contain as little gum residue as possible to prevent gum formation. Some fuels contain additives made up of aromatic amines and phenols to prevent formation of gum and varnish. During storage, harmful gum deposits may form due to the reaction of some fuel components with each other and with oxygen. Oxidation inhibitors are added to promote fuel stability and control gum and deposit formation. In aviation turbine fuels, large quantities of gum show contamination of fuel by higher boiling oils or particulate matter. A high existent gum content generally reflects poor handling practices in distribution downstream of the refinery.

Gum Formation

Gum formation (ASTM D525, IP 40) alludes to the formation of soluble organic material, whereas sediment is the insoluble organic material. Storage stability (or storage instability) (ASTM D381, ASTM D4625, IP 131, IP 378) is a term used to describe the ability of the liquid to remain in storage over extended periods of time without appreciable deterioration as measured by gum formation and/or the formation sediment. Thermal stability is also defined as the

ability of the liquid to withstand relatively high temperatures for short periods of time without the formation of sediment (i.e., carbonaceous deposits and/or coke). Thermal oxidative stability is the ability of the liquid to withstand relatively high temperatures for short periods of time in the presence of oxidation and without the formation of sediment or deterioration of properties (ASTM D2416), and there is standard equipment for various oxidation tests (ASTM D4171). Stability is also as the ability of the liquid to withstand long periods at temperatures up to 100°C (212°F) without degradation. Determination of the reaction threshold temperature for various liquid and solid materials might be beneficial (ASTM D2887).

Typically, gum is formed by any of the above-named reaction types during storage; some classes of hydrocarbons in fuel blends, particularly olefin derivatives and diolefin derivatives, are able to slowly react, at ambient temperatures, with the oxygen in the air. The oxidation products are responsible for the formation of an insoluble solid, commonly called deposits or gums, which sticks to the metal surfaces along the vehicle-fuel system, from the tank to the combustion chamber. Accumulation of these products can cause engine wear and can have adverse effects on engine efficiency, performance, emission, and durability. Consequently, it is necessary to predict fuel blend behavior and prevent gum formation, improving gasoline quality and using additives.

Hadley Cell

The Hadley cell is an air circulation pattern that dominates the tropical atmosphere, with rising motion near the equator, poleward flow 6 to 10 miles kilometers above the surface, descending motion in the subtropics, and flow near the surface toward the equator. This circulation is intimately related to the trade winds, tropical rain belts, subtropical deserts, and the jet streams.

The major driving force of atmospheric circulation is solar heating, which on average is largest near the equator and smallest at the poles. The atmospheric circulation transports energy in the direction of the poles, thereby reducing the resulting equator-to-pole temperature gradient. The mechanisms by which this is accomplished differ in tropical and extratropical latitudes. Between 30°N and 30°S latitude, this energy transport is accomplished by a relatively simple overturning circulation, with rising motion near the equator, poleward motion near the tropopause, sinking motion in the subtropics, and an equatorward return flow near the surface. In higher latitudes, the energy transport is instead accomplished by cyclones and anticyclones that cause relatively warm air to move toward the pole and cold air to move toward the equator in the same horizontal plane. The tropical overturning cell is referred to as the Hadley cell. Questions as to why it extends only to 30 degrees latitude and what determines its strength are at the heart of modern dynamical meteorology. The Hadley cell carries heat and moisture from the tropics to the northern and southern mid-latitudes. Near the tropopause, as the air moves toward the poles in the Hadley cell, it is turned eastward by the Coriolis force, which turns winds to the right in the Northern hemisphere and to the left in the Southern Hemisphere, creating the subtropical jet streams that flow from west to east.

As the ring of air moves toward the pole, it contracts closer to the axis of rotation so it must spin faster, which creates jets that rotate more rapidly than the Earth itself, which therefore appear as jets flowing from west to east with respect to the surface. Analogously, near the surface, the equatorward return flow is rotated to the west, or is slowed from the perspective of a non-rotating observer due to its movement away from the axis of rotation. These surface winds, with both an equatorward and a westward component, are referred to as the trade winds.

The region in which the equatorward moving surface flows converge and rise is known as the intertropical convergence zone (ITCZ) which is a high-precipitation band of thunderstorms. Having lost most of its water vapor to condensation and rain in the upward branch of the circulation, the descending air is dry. Low relative humidity is produced as the air is adiabatically warmed due to compression as it descends into a region of higher pressure. The subtropics are relatively free of the convection, or thunderstorms, that are common in the equatorial belt of rising motion. Many of the deserts of the world are located in these subtropical latitudes.

Halite

Halite (sometimes referred to as rock salt) is the natural mineral form of sodium chloride (NaCl), commonly known as and exists as isometric crystals. The mineral is typically colorless to yellow, but may also be light blue, dark blue, and pink depending on the amount and type of impurities. Halite commonly occurs with other evaporite deposit minerals such as several of the sulfates, halides, and borates.

Halite occurs in beds of sedimentary evaporite minerals that result from the drying up of enclosed lakes, playas, and seas. Halite is mainly a sedimentary mineral that usually forms in arid climates where ocean water evaporates. However, many inland lakes such as the Great Salt Lake of North America and the Dead Sea between Jordan and Israel are also locations where halite is forming. Over geologic time, several enormous salt deposits have been formed when repeated episodes of seawater evaporation occurred in restricted basins. Some of these deposits are thousands of feet thick. When buried deeply, they can erupt to form salt domes which are vertical diapirs (a domed rock

formations in which a core of rock has moved upward to pierce the overlying strata). Salt domes contain anhydrite (CaSO_4), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), and native sulfur, in addition to halite and the potassium mineral sylvite (KCl).

Halite is highly soluble, so dissolve in the presence of undersaturated water and when the halite dissolves, non-halite lithologies in the layered evaporite sequence remain as a layer of caprock at the top of the diapir. On continental margins, caprock is common onshore, may develop during major sea-level low-stands on the shelf, and is largely absent in deepwater settings. If the salt is exposed at the sea floor, dissolution occurs, but salt diapirs in deepwater are almost always covered by a thin veneer of hemipelagic mud that protects the halite from dissolution.

Halite forms an important cement in certain formations – especially those with a high formation water salt concentration. The challenge in cleaning samples containing halite is to remove salt from the pore water and yet not dissolve the natural halite cement. The selected cleaning method must remove the formation water and its salts without significantly affecting the native halite cement content. Methanol will dissolve both, so it is recommended to use iso-propyl alcohol (propan-2-ol, $\text{CH}_3\text{CHOHCH}_3$) as the solvent.

It is difficult (if not impossible) to avoid some dissolution of the native halite, but the relatively large surface area of the precipitated salts will cause them to be dissolved more rapidly than cementing halite, which has a relatively small exposure surface. As direct application of water-miscible solvents (such as methanol and iso-propyl alcohol) with saline pore brine can often cause precipitation, the initial stage of cleaning should therefore attempt to remove a significant volume of water prior to application of the iso-propyl alcohol.

Hardwood

In the current context of using wood as an alternate energy source, a description of the different types of pore system is worthy of note since the type of wood and the distribution patterns of the pore systems can have a strong influence the processibility of the wood.

Wood (also known as xylem) serves two functions in a standing tree. One function is to keep the tree standing tall and to withstand wind. The second function is to move water and nutrients from the soil to the leaves of the tree. After a tree has been harvested, water will continue to move in and out of the wood freely. There are three surfaces, or planes, that can be used to identify wood.

When a tree is cut down, the flat surface of the stump is the cross-sectional surface. The cross-sectional surface shows most of the cell types needed to identify wood. The tangential surface is the next most important surface, followed by the radial surface. There are several wood types within a tree. They are named based on when the wood was formed or where the wood is within the tree. Heartwood is the center of older trees and is often darker because of the chemicals deposited there as the tree ages. Sapwood is the younger wood in a tree and is active in transporting water and nutrients. It generally has a lighter color and is closer to the bark. Each year, trees add one growth ring. Each growth ring is usually two different colors. A lighter portion, called earlywood, is formed in the spring. Latewood is darker and formed in the summer. Figure 2 shows the difference in earlywood and latewood in a piece of Southern yellow pine

Thus, trees are classified into two different types: (i) hardwoods and (ii) softwoods. This classification has nothing to do with the wood itself, but with the type of leaves and flowers the tree has. Approximately 90 to 95% of softwood cells are called longitudinal tracheids because they transport water, and there are so few cell types in softwoods making it difficult to distinguish between types of softwoods. The structure of hardwoods is much more complex, and there is considerable variation from one species of tree to another in hardwoods. Hardwoods contain vessel elements, or pores, that softwoods do not have. Pores vary greatly; they can be (i) small, (ii) large, (iii) present in great numbers, or (iv) almost completely absent. If pores are present, the wood is a hardwood. If no pores are present, it is likely a softwood.

In addition, hardwoods can be classified into three groups based on the pores: (i) ring-porous hardwoods such as oaks and elms which have pores that transition from small to large abruptly from the earlywood to the latewood, (ii) semi-ring porous hardwoods, such as walnut, pecan, and hickory have pores that gradually change from small to large in a growth ring, and (iii) diffuse-porous hardwoods, such as yellow poplar, gum, and maple which have pores that are the same size throughout the growth ring. In addition, the pores are also distributed in other ways in wood and can be arranged as (i) solitary pores, which are individual pores that are evenly spaced, (ii) pore chains, which are multiple pores that are chained together, (iii) nested pores, which are clusters of pores that are connected together, (iv) multiple pore system in which two or more pores are clustered together, and (v) wavy bands, which are bands of pores with a wavy appearance.

Hazardous Air Pollutant

A hazardous air pollutant (HAP) is an air pollutant which presents, through inhalation or other routes of exposure, a threat of adverse human health effects or adverse environmental effects whether through ambient concentrations, bio-accumulation, deposition, or otherwise. Thus, hazardous air pollutants (HAPs) are air contaminants, frequently referred to as “air toxics,” that are known or suspected to cause serious human health effects or adverse environmental effects. Examples of hazardous air pollutants include benzene, trichloroethylene, mercury, chromium, and dioxin. The criteria air pollutants such as ozone and particulate matter are excluded from the hazardous air pollutants list.

Most air toxics originate from human-made sources, including mobile sources (such as automobiles, trucks, buses) and stationary sources (such as factories, refineries, power plants), as well as indoor sources (such as building materials and cleaning). There are two types of stationary sources that generate routine emissions of air toxics: (i) major sources and (ii) area sources.

Major sources typically are large industrial facilities such as chemical manufacturing plants, refineries, and waste incinerators. These sources may release air toxics from equipment leaks, when materials are transferred from one location to another, or during discharge through emission stacks or vents. Thus, major sources are defined as sources that emit 10 tons per year of any of the listed toxic air pollutants, or 25 tons per year of a mixture of air toxics. These sources may release air toxics from equipment leaks, when materials are transferred from one location to another, or during discharge through emission stacks or vents.

Area sources typically are smaller stationary facilities such as dry cleaners, auto body repair shops, and small manufacturing operations. These pollutants are typically emitted into the environment over the course of a year through normal emissions, fugitive releases, accidental releases, or plant upsets. The combination of volatile hydrocarbon derivatives and oxides of nitrogen also contribute to ozone formation, one of the most important air pollution problems. Thus area sources consist of smaller-size facilities that release lesser quantities of toxic pollutants into the air. Area sources are defined as sources that emit less than 10 tons per year of a single air toxic, or less than 25 tons per year of a combination of air toxics. Though emissions from individual area sources are often relatively small, collectively their emissions can be of concern - particularly where large numbers of sources are located in heavily populated areas. Though emissions from individual area sources often are relatively small, collectively they can be of concern, particularly where large numbers of sources are located in heavily populated areas.

Mobile sources include both on-road sources, such as cars, light trucks, large trucks, and buses, and non-road sources such as farm and construction equipment, lawn and garden equipment, marine engines, aircraft, and locomotives. Some hazardous air pollutants are also emitted from natural sources such as volcanoes.

Health effects associated with hazardous air pollutants include cancer, asthma and other respiratory ailments, birth defects, reproductive effects, and neurodevelopmental effects. However, although many hazardous air pollutants are of concern due to their potential to cause cancer, a substantial number of hazardous air pollutants lack evidence of cancer either because the relevant long-term studies have not been conducted, or because studies have been conducted and do not indicate carcinogenic potential.

Hazardous Chemicals

A hazardous chemical is any chemical which can cause a physical or a health hazard. Chemical hazards arise from the inherent (i) flammable, (ii) explosive, (iii) toxic, (iv) carcinogenic, (v) corrosive, (vi) radioactive, or (vi) reactive properties. The effect of exposure on personnel may be acute, e.g., in a flash-fire or due to inhalation of a high concentration of an irritant vapor. Alternatively, prolonged or intermittent exposure may result in an occupational disease or systemic poisoning. Generally, acute effects are readily attributable; chronic effects, especially if they follow a long latency period or involve some type of allergic reaction to a chemical, may be less easy to assign to particular occupational exposures. Chemicals displaying any of the above properties can lead to several effects and a combination of hazards. For example, personnel exposed to a fire may be subject to flames, radiant heat, spilled liquid chemicals and vapours from them, leaking gases, and the pyrolytic and combustion products generated from chemical mixtures together with oxygen deficient atmospheres.

However, whether a hazardous condition develops in any particular situation also depends upon the physical properties of the chemical (or mixture of chemicals), the scale involved, the circumstances of handling or use, e.g., the processes involved and degree of containment, and upon the control measures prevailing, e.g., provision of control and safety devices, local exhaust ventilation, general ventilation, personal protection, atmospheric monitoring, and systems of work generally.

The issues to be held in consideration are (i) the nature of the toxicity presented by the constituent, (ii) the concentration of the constituent in the waste, (iii) the potential of the constituent or any toxic degradation product of the constituent to migrate from the waste into the environment under the types of improper management, (iv) the persistence of the constituent or any toxic degradation product of the constituent, (v) the potential for the constituent or any toxic degradation product of the constituent to degrade into non-harmful constituents and the rate of degradation, (vi) the degree to which the constituent or any degradation product of the constituent accumulates in an ecosystem, (vii) the plausible types of improper management to which the waste could be subjected, (viii) the quantities of the waste generated at individual generation sites or on a regional or national basis, (ix) the nature and severity of the public health threat and environmental damage that has occurred as a result of the improper management of wastes containing the constituent, and (x) actions taken by other governmental agencies or regulatory programs based on the health or environmental hazard posed by the waste or waste constituent. Such lists of chemicals are not always complete, and omission of a chemical from this list does not mean it is without toxic properties or any other hazard. In fact, hazard recognition and assessment always commence from a knowledge of the individual properties of a chemical that are relevant to behavior on spillage or emission, and determination of permissible levels for disposal to air, land, or water systems. Other properties may be relevant, such as odor which can serve as a means of detection.

See also: Hazardous Air Pollutants.

Hazardous Waste

A hazardous waste is a waste with properties that make it dangerous or capable of having a harmful effect on human health or the environment. Hazardous waste is generated from many sources ranging from industrial manufacturing process wastes to batteries – even during the development of alternative energy sources – and may come in many forms, including gases, liquids, solids, and sludge.

Thus, a waste is a hazardous waste if it is specifically listed as a known hazardous waste or meets the characteristics of a hazardous waste. Listed wastes are wastes from common manufacturing and industrial processes and specific industries, and can be generated from discarded commercial products. Characteristic wastes are wastes that exhibit any one or more of the following characteristic properties: ignitability, corrosivity, reactivity, or toxicity.

The types of hazardous wastes classified by the United States Environmental Protection Agency in Subpart C of 40 CFR 61 consist of solid, liquid, and gaseous streams. They can be further classified as: (i) inorganic or organic, (ii) metal or non-metal, (iii) aqueous or non-aqueous, (iv) halogenated or non-halogenated, (v) ignitable or non-ignitable, (vi) corrosive or non-corrosive, (vii) reactive or non-reactive, and (viii) toxic or non-toxic.

However, many hazardous materials can display more than one of the above properties, and their waste streams become more complex through mixing a contamination as they pass down the waste hierarchy and get farther from the place at which they were generated. It is much simpler to recover materials for reuse when they have not been cross-contaminated with other hazardous wastes or for that matter any other wastes. Therefore, it is usually desirable to set use, recovery, and recycling equipment as near the waste generation site as possible and in any case to segregate waste streams to prevent cross-contamination.

Some waste streams are not compatible and should not be mixed unless special safety precautions have been taken to protect against the hazards generated by the mixing. An example of such incompatible waste streams is provided by an aqueous acid stream and a second stream containing either soluble sulfides or cyanides. Mixing would generate extremely toxic HCN or hydrogen sulfide gases. Such incompatible waste streams usually involve corrosive or reactive wastes as one of the waste streams.

In many cases, the feedstocks to separation processes were classified as (i) heterogeneous or (ii) homogeneous. Typically, heterogeneous streams are usually relatively easy to separate into their respective phases. When phase separation alone provides the necessary recovery process, as is often the case with oily wastewaters, recovery of valuable materials can be achieved by the use of coalescing and settling devices. However, homogeneous waste streams require more complex processes such as distillation, extraction, or adsorption for recovery of valuable materials.

See also: Hazardous Chemicals, Waste.

H-Coal Process

The H-coal process is an extension of the ebullated-bed technology that is used to convert coal, heavy crude oil, and residua into lower boiling liquid products. The process also has the potential to be adaptable for the conversion of certain types of biomass and/or waste to low-boiling liquid products. There is also the potential for the process to be adapted to the conversion of biomass and/or waste to renewable fuels.

In the process, the feedstock is crushed, slurried with oil (usually recycle oil from the process) and pumped to a pressure of up to 3,000 psi after which the mixture is preheated and introduced into the bottom of the ebullated-bed reactor. The overhead products are fractionated into gases, low-boiling distillate, and high boiling-distillate. The process conditions (which may be 345 to 370°C; 650 to 700°F) can be altered appropriately to accommodate different feedstocks and to produce different product slates. For example, synthetic crude production usually requires higher temperatures and higher hydrogen (partial) pressures than the process conditions for the production of low-sulfur residual oils in addition; this latter operational mode requires that less hydrogen be consumed.

See also: Biomass, waste.

Heat Balance

Every chemical process involves the transfer of energy, typically in the form of heat. For example, the distillation process involves phase changes in which energy is added for volatilization at reboiler and energy removed at condenser which the amount of energy that flows into or out of each process unit, that must be added or removed. Heat balance calculations are usually carried out when developing new chemical processes and improving old ones, because no process can work if too much heat is released or if there is a lack of thermal energy to maintain the reaction temperature.

The heat balance of, for example, the combustion process provides a relative weighting of the heat input into the system versus the heat output of the process:

$$dH_I \rightarrow dH_c + S_H + dH_E$$

In this equation, dH_c is the heat input, S_H is a composite of the sensible and latent heats of air, fuel, and other materials, and dH_E is the heat from exothermic reactions (other than combustion) which may contribute to the overall combustion process:

$$dH_o \rightarrow dH_{cu} + S_{HC} + dH_{-E} + dS_{AG} + dH_L$$

dH_o is the heat output, dH_{cu} is the heat of combustion of unburned fuel, S_{HC} is the sensible and latent heats in the carbonization products, dH_{-E} is the heat absorbed by endothermic reactions, dS_{AG} is the sensible and latent heats in the combustion products (ash and stack gases), and dH_L is the heat losses to the surroundings by convection, radiation, and combustion.

The presence of water vapor in the combustion system appears in the latent heat effects, and one consequence of high moisture content in coal combustion is that a part of the heat is lost due to evaporation of the moisture in the coal and is not recouped from the combustion products.

A small amount (<5% w/w) of water in the feedstock (such as biomass) may not exert any marked effect on the overall heat requirements, since the sensible heat of the gases vaporizes the water.

Heat Capacity

The heat capacity of the feedstock is the heat required to raise the temperature of one unit weight of the feedstock by one degree.

The heat capacity can be measured by standard calorimetric methods that have been developed for other materials (ASTM C351). The units for heat capacity are Btu per pound per degree Fahrenheit (Btu/lb/°F) or calories per gram per degree centigrade (cal/g °C), but the specific heat is the ratio of two heat capacities and is therefore dimensionless.

The heat capacity of water is 1.0 Btu/lb °F and the heat capacity of any material will always be numerically equal to the specific heat. Consequently, there has been the tendency to use the terms heat capacity and specific heat almost equivocally.

The specific heat usually increases with its moisture content, decreases with carbon content, and increases with volatile matter content, with mineral matter content exerting a somewhat lesser influence. The values for the specific heat of various coals fall into the general range 0.25 to 0.37 but, as with other physical data, comparisons should only be made on an equal basis (e.g., moisture content, mineral matter content, etc.).

Estimates of the specific heat have also been made on the assumption that the molecular heat of a solid material is equal to the sum of the atomic heats of the constituents (Kopp's law); the atomic heat so derived is divided by the atomic weight to give the (approximate) specific heat. Thus, using coal as the example, it has been possible to derive a formula that indicates the relationship between the specific heat and the elemental analysis of coal (mineral-moisture-free basis, mmf basis):

$$C_p = 0.189C + 0.874H + 0.491N + 0.360O + 0.215S$$

C, H, N, O, and S are the respective amounts (% w/w) of the elements in the coal.

See also: Kopp's Law.

Heat Content

The heat content or calorific value of a material is a direct indication of the heat content (energy value) of the material and a means by which coal can be evaluated.

The heat content of a feedstock (usually presented in Btu/lb) is a direct indication of the energy value of the feedstock and represents the combined heat of combustion of the carbon, hydrogen, nitrogen, and sulfur in the organic.

In the present context, the importance of the calorific value is one of the means by which biomass and fuels can be evaluated (for example, Table H-1).

Table H-1 Heat content (calorific value, btu/lb) of selected hydrocarbons and fuels.

Fuel	Heat content, Btu/lb
Acetylene	20,734
Bagasse (sugar cane)	6,500
Biomass (corn stover, dry)	7,000
Biomass (forest residue, dry)	6,600
Biomass (herbaceous, dry)	7,400
Butane	19,679
Carbon monoxide	4,346
Ethane	20,431
Ethylene	20,276
Hydrogen	51,593
Methane	21,518
Natural gas*	21,150
Producer gas	2,280
Rice Hulls	6,580
Poultry litter	6,180
Propane	19,944
Switchgrass	7,300
Wood (farmed trees, dry)	8,400
Wood (forest residue, dry)	8,400
Crude oil*	18,000
Heavy oil*	16,000
Coal (anthracite)*	14,000
Coal (bituminous)*	11,000
Coal (lignite)*	8,000

*Included for comparison.

The calorific value is a complex function of the elemental composition and is usually reported as the gross calorific value with a correction applied if the net calorific value is of interest.

Depending on the material, it is possible to make a close estimation of the calorific value (CV) by means of various formulae (that have been developed for coal and might require some modification), the most popular of which are:

The Dulong formula:

$$CV = 144.4(\%C) + 610.2(\%H) - 65.9(\%O) - 0.39(\%O)$$

The Dulong-Berthelot formula:

$$CV + 81370 + 345 [\%H - (\%O + \%N - 1)/8] + 22.2(\%S)$$

%C, %H, %N, %O, and %S are the respective carbon, hydrogen, nitrogen, oxygen, and organic sulfur contents of the material (all of which are calculated to a dry, ash-free basis).

In terms of energy content and energy density, There are two kinds of heat of combustion: (i) the higher value (HHV), or gross heat of combustion, includes all the heat released as the products cool to room temperature and whatever water vapor is present condenses, and (ii) the lower value (LHV), or net heat of combustion, does not include the heat which could be released by condensing water vapor, and may not include the heat released on cooling all the way down to room temperature.

See also: Energy Density, Higher Heating Value, Lower Heating Value.

Heat Exchangers

Heat exchangers transfer heat from one working fluid to another. For instance, steam generators, feedwater heaters, reheaters and condensers are all examples of heat exchangers found in nuclear power systems. The heat transfer rate across a heat exchanger is usually expressed in the form:

$$Q = UA\Delta T_m$$

Q is the heat transfer rate, U is the overall heat transfer coefficient, A is the heat exchanger area, and ΔT_m is the average temperature difference between the fluids Table H-2).

Table H-2 Various types of gas-liquid heat exchangers.

Driving force	Change of phase	Examples
Gravity	No	Spray columns, packed columns
	Yes	Cooling towers, falling droplet evaporators
Forced	No	Spray coolers/quenchers
Liquid flow	Yes	Spray condensers/evaporation
Gravity	No	Bubble columns, perforated tray columns
	Yes	Bubble column condensers
Forced	No	Gas spargers
Gas flow	Yes	Direct contact evaporators

However, heat exchangers exist in three primary forms: (i) parallel flow heat exchangers, (ii) counter-flow heat exchangers, and (iii) cross-flow heat exchangers. classifications of heat exchangers according to their flow arrangement.

In *parallel-flow* heat exchangers, the two fluids enter the exchanger at the same end, and travel in parallel to one another to the other side. In *counter-flow* heat exchangers, the fluids enter the exchanger from opposite ends. The countercurrent design is the most efficient, in that it can transfer the most heat from the heat (transfer) medium per unit mass due to the fact that the average temperature difference along any unit length is *higher*. In a *cross-flow* heat exchanger, the fluids travel roughly perpendicular to one another through the exchanger.

Heat exchangers are designed to maximize the surface area of the wall between the two fluids, while minimizing resistance to fluid flow through the exchanger. The exchanger's performance can also be affected by the addition of fins or corrugations in one or both directions, which increase surface area and may channel fluid flow or induce turbulence.

Direct contact heat exchangers involve heat transfer between hot and cold streams of two phases in the absence of a separating wall. Thus such heat exchangers can be classified as: (i) gas-liquid, (ii) immiscible liquid-liquid, and (iii) solid-liquid or solid-gas. Most direct contact heat exchangers fall under the gas-liquid category, where heat is transferred between a gas and liquid in the form of drops, films or sprays. In the petroleum and natural gas industry, these types of heat exchangers are used predominantly in liquid heating, water cooling and, condensing.

For an adiabatic heat exchanger (no heat transferred with environment), there are three equations for Q , i.e., the rate of heat exchange between the two process streams:

$$Q = N_{ps} (H_{ps,in} - H_{ps,out}) \text{ (heat transferred from process stream)}$$

$$Q = N_{us} (H_{us,out} - H_{us,in}) \text{ (heat transferred to utility stream)}$$

$$Q = UAF\Delta T_{avg} \text{ (rate of heat transfer; actually defining } U)$$

Q is the rate of heat exchange (e.g., in kJ/h), N_i is the flowrate of stream i (e.g., in kmol/h), H_i is the specific enthalpy of stream i (kJ/kmol), U is the overall heat transfer coefficient (kJ/m²K), A is the heat exchange area (m²), F is the correction factor for the deviation from cocurrent or countercurrent flow, ΔT_{avg} is the average temperature difference between the streams for true cocurrent or countercurrent flow.

If both streams exchange either latent heat or sensible heat, but not both, then:

$$\Delta T_{avg} = \Delta T_{lm} \equiv \frac{\Delta T_{end1} - \Delta T_{end2}}{\ln \Delta T_{end1} - \ln \Delta T_{end2}}$$

for both cocurrent and countercurrent flow, where: ΔT_{end1} is the temperature difference between the two streams at end 1 of the column (K), ΔT_{end2} is the temperature difference between the two streams at the end 2 of the column (K). Either end of the heat exchanger can be designated as 1 or 2.

Heating Value

The heating value (heat content, calorific value, or energy value) of a substance, usually a fuel, is the amount of heat released during the combustion of a specified amount of it.

The lower heating value (usually represented as LHV, also known as net calorific value) of a fuel is defined as the amount of heat released by combusting a specified quantity (initially at 25°C, 77°F) and returning the temperature of the combustion products to 150°C (300°F), which assumes the latent heat of vaporization of water in the reaction products is not recovered.

The higher heating value (usually represented as HHV, also known gross calorific value or gross energy) of a fuel is defined as the amount of heat released by a specified quantity (initially at 25°C, 77°F) once it is combusted and the products have returned to a temperature of 25°C (77°F), which takes into account the latent heat of vaporization of water in the combustion products.

See also: Calorific Value, Heat Content.

Heat of Combustion

The gross heat of combustion is given with fair accuracy by the equation:

$$Q = 12,400 - 2100d^2$$

Where d is the 60/60°F specific gravity. Deviation is generally less than 1%, although many highly aromatic feedstocks may show considerably higher values.

For thermodynamic calculation of equilibria useful in hydrocarbon research, combustion data of extreme accuracy are required because the heats of formation of water and carbon dioxide are large in comparison with those in the hydrocarbon derivatives. Great accuracy is also required of the specific heat data for the calculation of free energy or entropy. Much care must be exercised in selecting values from the literature for these purposes, since many of those available were determined before the development of modern calorimetric techniques.

See also: Heat Balance.

Heavy Metals

Heavy metals are those metals that have relatively high density, atomic weight, or atomic number. As an example, a density that is higher than 5 g/cm³ is often used as a guide to the definition of the heavy metals. However, the physical and chemical characterization of heavy metals need to be treated with caution, as the metals involved are not always consistently defined. While it is relatively easy to distinguish a heavy metal such as tungsten from a lower atomic weight metal such as sodium, a few heavy metals, such as zinc, mercury, and lead, have some of the characteristics of lower atomic weight metals, and lower atomic weight metals such as beryllium, scandium, and titanium have some of the characteristics of the higher atomic weight metals.

Heavy metals are natural elements characterized by their rather high atomic mass and their high density. Although typically occurring in rather low concentration, they can be found all through the crust of the Earth. Commonly, a density of at least 5 g cm⁻³ is used to define a heavy metal and to differentiate it from other, lower atomic weight metals. Other, broader definitions for "heavy metals" require an atomic mass higher than 23 or an atomic number exceeding 20; these definitions are highly error-prone and confusing.

Examination of the periodic table of elements (Table H-3) shows that (according to the density criterion) heavy metals occupy columns 3 to 16, of the periods 4 to 6, encompassing the transition metals, post-transition metals, and lanthanides.

Table H-3 The Periodic Table of the Elements.

Some heavy metals – such as copper, selenium, or zinc – are essential trace elements, with functions indispensable for various biological processes also driving the entire human metabolism. The heavy metal cobalt, acting as the central atom in the vitamin B12 complex, is a key player in the reductive branch of the propionic acid fermentation pathway.

Many heavy metals such as iron, zinc, tin, lead, copper, and tungsten are of outstanding technological significance insofar as the metal acts as the central atom of bioinorganic catalysts for special chemical transformations. However, many of the heavy metals such as mercury, cadmium, arsenic, chromium, thallium, lead, and others exert toxic effects, even at low concentration.

There are some trace elements among the heavy metal family, which are essential for many biological processes; they are predominantly found in Period 4 of the Periodic Table of Elements. For strict aerobic beings as humans are, it would not be possible to survive without having cytochromes, which make aerobic life forms breathe since the very beginning. Iron also plays a major role in the human respiration system as the central atom of the blood pigment heme. Copper plays a similar role in the transport of electrons and oxygen, especially as the central atom in hemocyanin in mollusks and arthropods. Zinc in turn is pivotal as a constituent of some enzymes. Selenium is described as an antioxidant; further, it is involved in hormone biosynthesis. Cobalt was found to be significant in the biosynthesis of complex compounds and different steps in cellular metabolism, especially as the central atom in vitamin B12, which is needed for cell division, blood formation, the nervous system, and in propionic acid biosynthesis. Moreover, vanadium and manganese are important for regulation and functioning of several enzymes, whereas some metabolic functions are also assigned to the typically known-as-toxic elements chromium, arsenic, and nickel. Regarding arsenic, this element was only recently revealed as a natural constituent in herring caviar, where it was shown to substitute phosphorus in phosphatidylcholine-like lipids, the so-called arseno-lipids. Further, molybdenum plays a role in some redox reactions, in addition to the function of cadmium in the metabolism of some microalgae from the Diatomophyceae class.

Significantly elevated levels of inorganic pollutants, of which the so-called heavy metals are prominent, often occur in soils from previously heavily industrialized areas. These sites produced wastes contaminated with heavy metals, arsenic, and antimony. Following the decline of heavy manufacturing, many industrial sites have been abandoned and remain so without remedial works to their contaminated and often phytotoxic substrates.

Toxic metals, such as lead (Pb), are problematic contaminants in soils, surface waters, recent sediments, and aerosols, mainly in urban environments. Toxic metals occur naturally in mining areas, but the mining activities reinforce their release into the environment. Because of their limited mobility, toxic metals are less frequent in groundwater and often form cations (such as divalent lead, Pb^{2+}) that are prone to adsorption, or they precipitate as difficult-to-dissolve oxide derivatives, sulfide derivatives, or other minerals. Some metal cations are more mobile in the environment such as cadmium (Cd^{2+}), which is also highly toxic. Mercury is extremely toxic and specific bacteria can convert it into the highly mobile methyl mercury ion (HgCH_3^+) or volatile dimethyl mercury [$\text{Hg}(\text{CH}_3)_2$]. In karst systems, sediments in conduits and caves can act as reservoirs for toxic metals and other contaminants; during high-flow events, they can be mobilized and conducted toward large springs.

Arsenic (As) is a toxic metal that causes large-scale groundwater contamination and diseases in several regions of the world. Natural arsenic contamination occurs in arid to semiarid inland basins and in reducing alluvial aquifers, that is, in flat, low-lying areas, where groundwater is sluggish and often exploited by deep pumping wells. Arsenic-rich water is also found in mining areas; in the past, it was also used for insecticides, some of which might still be in use in some regions.

Modern physical and chemical approaches for remediation of heavy metal pollution involve the use of adsorption on new adsorbents such as nano-carriers, ion exchange techniques, removal via advanced membrane filtration techniques, electrodialysis, or photocatalysis. Among these novel physicochemical techniques, new adsorption- and membrane filtration-based methods are most thoroughly investigated and are most commonly applied to treat contaminated wastewater. Among new absorbents, both inorganic (kaolinite, montmorillonite) and organic materials (such as agricultural waste or bio-char) were studied for heavy metal recovery. In this context, the application of carbon-based, metal-based, or metal oxide-based nanoparticles as adsorbents benefits from high surfaces susceptible toward metal adsorption and expedient reactivity. The mechanisms of interactions of nanomaterials with, on the one hand, heavy metals and, on the other hand, heavy metal with additional wastewater constituents with metal-binding groups need to be understood in order to optimize the recovery processes.

Heavy Oil

Heavy oil (heavy crude oil) is a type of crude oil that is different from conventional crude oil insofar as they are much more difficult to recover from the subsurface reservoir. Heavy crude oil, particularly heavy crude oil formed by biodegradation of organic deposits, is found in shallow reservoirs, formed by unconsolidated sands. This characteristic, which causes difficulties during well drilling and completion operations, may become a production advantage due to higher permeability. In simple terms, heavy crude oil is a type of crude oil which is very viscous and does not flow easily. The common characteristic properties (relative to conventional crude oil) are high specific gravity, low hydrogen-to-carbon ratios, high carbon residues, and high contents of asphaltenes, heavy metal, sulfur, and nitrogen. Specialized refining processes are required to produce more useful fractions, such as: naphtha, kerosene, and gas oil.

Heavy crude oil has a much higher viscosity (and lower API gravity, typically on the order of $<20^\circ$ API) than conventional crude oil, and recovery of heavy crude oil usually requires thermal stimulation of the reservoir. When crude oil occurs in a reservoir that allows the crude material to be recovered by pumping operations as a free-flowing dark-to-light-colored liquid, it is often referred to as conventional crude oil.

The term heavy crude oil has also been arbitrarily (incorrectly) used to describe both the heavy crude oils that require thermal stimulation of recovery from the reservoir and the bitumen in bituminous sand (tar sand) formations from which the viscous bituminous material is recovered by a mining operation. Extra heavy crude oil is a non-descript term (related to viscosity) of little scientific meaning, which is usually applied to tar sand bitumen and, like tar sand bitumen, is generally incapable of free flow under typical (low temperature) reservoir conditions.

Heavy Water Reactor

The heavy water reactor (HWR) differs in the design of the core, fuel, moderator, and coolant and the orientation of the core of the reactor which is horizontal inside a tank that consists of fuel channels. The reactor can be refueled during operation, using the natural uranium as fuel, and utilizing the heavy water as a coolant and moderator. Same as for pressurized water reactors, the heat is exchanged between the primary and secondary loop through a heat exchanger.

A pressurized heavy-water reactor (PHWR) is a nuclear reactor that uses heavy water (deuterium oxide, D_2O) as the coolant and neutron moderator. This types of reactor frequently use natural uranium as fuel, but can also use a low-enriched uranium. The heavy water coolant is kept under pressure to avoid boiling, allowing it to reach higher temperature (mostly) without forming steam bubbles, exactly as for the pressurized water reactor. The low absorptivity of the heavy water for neutrons greatly increases the neutron economy of the reactor, thereby avoiding the need for enriched fuel.

See: Nuclear Reactor – Heavy Water Reactor.

Helium-3

Helium-3 (3He) is a non-radioactive isotope of helium with two protons and one neutron. It is rare on Earth, and it is sought for use in nuclear fusion research. The nucleus of a helium-3 atom, consists of two protons but only one neutron, in contrast with two neutrons in common helium.

Because of the lower atomic mass (3.02 atomic mass units), helium-3 has some physical properties different from those of helium-4 (4.00 atomic mass units). Because of the weak, induced dipole–dipole interaction between helium atoms, their macroscopic physical properties are mainly determined by their zero-point energy (ground-state kinetic energy). Also, the microscopic properties of helium-3 cause it to have a higher zero-point energy than helium-4. This implies that helium-3 can overcome dipole–dipole interactions with less thermal energy than helium-4 can.

Helium-3 boils at $270^\circ C$ ($456^\circ F$) compared with helium-4 at $267^\circ C$ ($452^\circ F$) and the critical point is also lower at $270^\circ C$ ($454^\circ F$), compared with helium-4 at $268^\circ C$ ($450^\circ F$). Helium-3 has less than one-half of the density when it is at its boiling point: 59 gram per liter compared to the 125 gram per liter of helium-4 at a pressure of one atmosphere.

Helium-3 (^3H) can be used in fusion reactions by either of the reactions such as the reaction with deuterium (^2H) or with itself:

The conventional deuterium + tritium (D-T, ^2H - ^3H) fusion process produces energetic neutrons which render reactor components radioactive with activation products. The appeal of helium-3 fusion stems from the aneutronic nature of its reaction products, and helium-3 is non-radioactive. The lone high-energy by-product, the proton, can be contained using electric and magnetic fields. The momentum energy of this proton (created in the fusion process) will interact with the containing electromagnetic field, resulting in direct net electricity generation.

Because of the higher Coulomb barrier, the temperatures required for $^2_1\text{H} + ^3_2\text{He}$ fusion are much higher than those of conventional D-T fusion. Moreover, since both reactants need to be mixed together to fuse, reactions between nuclei of the same reactant will occur, and the D-D reaction ($^2_1\text{H} + ^2_1\text{H}$) does produce a neutron. Reaction rates vary with temperature, but the deuterium-helium-He-3 reaction rate is lower than the D-D reaction rate. Therefore, fusion using D- ^3He fuel may produce a somewhat lower neutron flux than D-T fusion.

The second possibility, fusing ^3_2He with itself ($^3_2\text{He} + ^3_2\text{He}$), requires even higher temperatures (since now both reactants have a +2 charge), and thus is even more difficult than the D- ^3He reaction. However, it does offer a possible reaction that produces no neutrons; the protons it produces possess charges and can be contained using electric and magnetic fields, which in turn results in direct electricity generation.

The amounts of helium-3 needed as a replacement for conventional fuels are substantial by comparison to amounts currently available. The total amount of energy produced in the $^2\text{H}_1 + ^3_2\text{He}$ reaction is 18.4 MeV. If the total amount of energy could be converted to electrical power with 100% efficiency (a physical impossibility), it would correspond to approximately 30 minutes of output of a gigawatt electrical plant per mole of ^3He .

Hemicellulose

Unlike cellulose, hemicellulose derivatives consist of different monosaccharide units. In addition, the polymer chains of hemicellulose derivatives have short branches and are amorphous. Because of the amorphous morphology, hemicellulose derivatives are partially soluble in water. Hemicellulose derivatives are related to plant gums in composition, and occur in much shorter molecule chains than cellulose. The hemicellulose derivatives, which are present in deciduous woods chiefly as pentosan and in coniferous woods almost entirely as hexosan, undergo thermal decomposition very readily. Hemicellulose derivatives are derived mainly from chains of pentose sugars, and act as the cement material holding together the cellulose micelles and fiber.

The backbone of the chains of hemicellulose derivatives can be a homopolymer (generally consisting of a single sugar repeat unit) or a heteropolymer (a mixture of different sugars). Among the most important sugar of the hemicellulose derivatives component is xylose. In hardwood xylan, the backbone chain consists of xylose units which are linked by β -(1,4)-glycoside bonds and branched by α -(1,2)-glycoside bonds with 4-O-methyl glucuronic acid groups. In addition, O-acetyl groups sometimes replace the OH groups in position C_2 and C_3 . For softwood xylan, the acetyl groups are fewer in the backbone chain, but softwood xylan has additional branches consisting of arabinofuranose units linked by α -(1,3)-glycoside bonds to the backbone. Hemicellulose derivatives are largely soluble in alkali and, as such, are more easily hydrolyzed.

Hemp

Hemp is an annual short day, C3 plant with a high cellulose and lignin content in its stems and a high fat and protein content in its seeds. The entire plant consisting of bast fibers, leaves, seeds, and processable remains can be used as a

solid fuel when compacted. The stalk contains a strong and durable fiber. The average height is 2.5 meters, but it can reach up to 4 meters height. For the energetic use, the whole hemp crop is harvested. Direct harvesting by a forage harvester was tested.

Hemp can be easily planted and cultivated, but its growing is prohibited in some EU countries as it can be used as a drug. The plants vegetative period is approximately 100 days, with the main growth period in June and July, followed by flowering in August. The yields are high (18 t/ha), but the high plant moisture content can create storage problems.

Two different harvesting technologies are available for the energy use of the whole hemp crop. The first is the whole-fiber-technology where, with a modified chopping technology, the hemp culm is cut into 50 to 60 cm lengths. The straw stays for four weeks on the field for drying before the bales are pressed. Another technology is wet harvesting. This technology includes the chopping of the crops followed by silaging. For combustion, it is necessary to press the hemp silage into bales to reduce the water content of the fuel.

Herbaceous Biomass

The energy application of herbaceous biomass has a high potential because most of it represents residual material from agriculture (straw), which could be available at a relatively low cost.

The transformation of herbaceous raw material into a feedstock for gasification is simpler than that of woody raw material since herbaceous biomass only requires chaffing. Hence, unlike woody biomass, a distinction between raw material and feedstock is not made for herbaceous biomass. The main herbaceous species currently considered for energy application are miscanthus, reed canary grass, and switchgrass.

Miscanthus is an attractive option, since growing requires lower input of fertilizers and pesticides compared to agricultural crops, while yields can reach 15 tonnes per hectare per year under optimum conditions. Its main disadvantage is that it can be difficult to rehabilitate the land for other uses due to the deep root structure of miscanthus. Slightly lower maximum yields (up to 4 ton per acre per year) are earned from switchgrass. Canary grass gives even lower yields (less than 2 tons per acre per year) without the need for crop rotation for approximately 10 years, but it fits well the climate conditions of northern countries. Canary grass is however very invasive of wetlands and is not a suitable alternative to agricultural crops on high grades of arable land.

Compared to short-rotation forestry, herbaceous species have lower moisture content and under certain conditions can be slightly cheaper. However, herbaceous species show some disadvantages compared to woody biomass: lower bulk density, which increases transportation and handling costs; a larger content of undesirable compounds (potassium, chlorine, sulfur, ash), which reduces the yield of synthesis gas, may cause corrosion, agglomeration, intensive slagging and fouling, etc. For these reasons, herbaceous biomass usually is not directly gasified for BTL production, but it is processed into a semi-finished product – pyrolysis oil.

See also: Herbaceous Crops.

Herbaceous Crops

Growing dedicated herbaceous crops for energy purposes is a relatively novel practice, thus complete information related to the various aspects of their cultivation is still scarce. The main herbaceous species currently considered in Europe for energy application are miscanthus, red canary grass, and switchgrass. Miscanthus is an attractive option, since growing requires lower input of fertilizers and pesticides compared to agricultural crops, while yields can reach 6 tons per acre per year under optimum conditions. Its main disadvantage is that it can be difficult to rehabilitate the land for other uses due to the deep root structure of miscanthus. Slightly lower maximum yields (up to 10 tonnes per hectare per year) are earned from switchgrass. Red canary grass gives even lower yields per hectare per year (5 to 7 tons) without the need for crop rotation for approximately 10 years. Red canary grass is however very invasive of wetlands and is not a suitable alternative to agricultural crops on high grades of arable land.

Compared to short-rotation forestry, herbaceous species have lower moisture content and under certain conditions can be slightly cheaper. However, herbaceous species show some disadvantages compared to woody biomass: lower bulk density, which increases transportation and handling costs; a larger content of undesirable compounds (potassium, chlorine, sulfur, ash), which reduces the yield of synthesis gas, may cause corrosion, agglomeration, intensive slagging and fouling, etc. For these reasons, herbaceous biomass usually is not directly gasified for BTL production, but it is processed into a semi-finished product – pyrolysis oil.

Heteroatom Compounds

The term heteroatom compounds is usually used more specifically to indicate that non-carbon atoms have replaced carbon in the backbone of the molecular structure of a hydrocarbon derivative. Typical heteroatoms are nitrogen, oxygen, and sulfur and, to a lesser extent phosphorous, chlorine as well as various metals that are bound within the organic structure.

When present in organic compounds, atoms other than carbon and hydrogen are called hetero-atoms. Sulfur, nitrogen, oxygen, and metals are minor constituents of crude oil, but their impact on processing costs can be major. When burned in vehicles or power plants, high-sulfur fuels lead to the production of sulfur oxides and, eventually, cause acid rain. For many refining processes, sulfur is a catalyst poison. Nitrogen and metals also are catalyst poisons. Therefore, refiners devote a considerable amount of time and money to remove hetero-atoms from intermediate streams and finished products.

Within the class of heteroatom compounds are a class of compounds known as heterocyclic compounds which are any of a major class of organic chemical compounds characterized by the fact that some or all of the atoms in these molecules are joined in rings containing at least one atom of an element other than carbon. In the general structure, heterocyclic compounds resemble cyclic organic compounds that incorporate only carbon atoms in the rings but the presence of the heteroatoms (nitrogen, oxygen, or sulfur) gives heterocyclic compounds physical and chemical properties that are often quite distinct from those of their all-carbon-ring analogs.

Heterogeneous Catalyst

Catalysts can be divided into two main types – homogeneous and heterogeneous. In a homogeneous reaction, the catalyst is in the same phase as the reactants. A heterogeneous catalyst is a catalyst that exists in a different phase to the reactants. Heterogeneous catalysts provide a surface on which the reaction may take place.

In heterogeneous catalysis, in order for the reaction to occur, one or more of the reactants must diffuse to the catalyst surface and adsorb onto it. After reaction, the products must desorb from the surface and diffuse away from the solid surface. Frequently, this transport of reactants and products from one phase to another plays a dominant role in limiting the reaction rate. If diffusion rates are not taken into account, the reaction rates for various reactions on the catalyst surface depend solely on the rate constants and reactant concentrations. Asymmetric heterogeneous catalysis can be used to synthesize enantiomerically pure compounds using chiral heterogeneous catalysts.

Heterogeneous catalysts are typically supported insofar as the catalyst is dispersed on a second material that enhances the effectiveness or minimizes their cost. Sometimes, the support is merely a surface upon which the catalyst is spread to increase the surface area. More often, the support and the catalyst interact, affecting the catalytic reaction.

There are two types of heterogeneous catalyst: zeolite and amorphous catalysts. The difference between them is that zeolite catalysts are more active in cracking than amorphous catalysts due to its higher acidity in both strength and number of acid sites. Zeolite-based catalysts are also highly selective toward industrial products. For a given conversion of feedstock, the amorphous catalysts require a substantially higher operating

temperature than the zeolite-containing catalysts. Another major advantage of the zeolite catalysts is their lower rate of deactivation.

Heterosphere

The heterosphere is the layer of an atmosphere where the gases are separated out by molecular diffusion with increasing altitude such that less dense constituents become more abundant relative to higher density constituents. The higher density constituents tend to be present in the lower layers of the heterosphere (density segregation or density stratification), while the lower density constituents are present at higher elevations. The exact boundaries between the different molecules vary according to temperature and solar activity. The heterosphere extends from the turbopause to the edge of the atmosphere and lies directly above the homosphere.

High-Btu Gas

High-Btu gas consists predominantly of methane with a heating value of approximately 1,000 Btu/scf. It is also referred to as substitute (or synthetic) natural gas (SNG) depending on the origin of the gas. High-Btu gas consists mainly of pure methane (>95%), and as such, its heating value is around 900 to 1,000 Btu/scf.

This type of synthesis gas is usually produced by catalytic reaction of carbon monoxide and hydrogen, which is called methanation reaction. The feed synthesis gas usually contains carbon dioxide and methane in small amounts. Further, steam is usually present in the gas or added to the feed to alleviate carbon fouling that affects the catalytic effectiveness. Therefore, the pertinent chemical reactions in the methanation system include:

Among the above reactions, the most dominant chemical reaction leading to methane is the first one. Therefore, if methanation is carried out over a catalyst with a synthesis gas mixture of hydrogen and carbon monoxide, the desired hydrogen-to-carbon monoxide ratio of the feed synthesis gas is on the order of 3:1. The large amount of water produced is removed by condensation and recirculated as process water/steam. During this process, most of exothermic heat due to the methanation reaction is also recovered via a variety of energy integration processes. While all the reactions listed above are quite strongly exothermic except the forward water gas shift reaction being mildly exothermic, the heat release depends largely on the amount of carbon monoxide present in the feed synthesis gas. For each 1% of carbon monoxide in the feed synthesis gas, an adiabatic reaction will experience a 60°C (140°F) temperature rise, which may be termed as adiabatic temperature rise.

A variety of metals exhibit catalytic effects on methanation reaction. In the order of catalytic activity, $\text{Ru} > \text{Ni} > \text{Co} > \text{Fe} > \text{Mo}$. Nickel is by far the most commonly used catalyst in commercial processes because of its relatively low cost and also of reasonably high catalytic activity. Nearly all the commercially available catalysts used for this process are, however, very susceptible to sulfur poisoning, and efforts must be spent to remove all hydrogen sulfide (H_2S)

before the catalytic reaction starts. It is necessary to reduce the sulfur concentration in the feed gas to lower than 0.5 ppm in order to maintain adequate catalyst activity for a long period of time.

Some of the noteworthy commercial methanation processes include Comflux process, HICOM process, and Direct Methanation process.

The Comflux process is a Ni-based, pressurized fluidized bed (PFB) process converting carbon monoxide-rich gases into synthetic natural gas (CH_4) in a single stage, where both methanation and water gas shift reaction take place simultaneously. The HICOM process developed by British Gas Corporation is a fixed bed process, which involves a series of methanation stages using synthesis gas with a relatively low hydrogen- to-carbon monoxide ratio. Direct methanation is a process developed by Gas Research Institute (GRI), which methanates equimolar mixtures of H_2 and CO , producing CO_2 rather than H_2O (steam) in addition to methane:

The catalyst developed is claimed to be unsusceptible to sulfur poisoning, and as such, the process can be used to treat the raw, quenched gas from a coal gasifier with no or little pretreatment.

Higher Heating Value

The higher heating value (HHV; also known as the gross calorific value or gross energy) of a fuel is the amount of heat released during combustion by a specified quantity (initially at 25°C) and the products have returned to a temperature of 25°C .

The higher heating value takes into account the latent heat of vaporization of water in the combustion products, and is useful in calculating heating values for fuels where condensation of the reaction products is practical (e.g., in a gas-fired boiler used for space heat) and assumes all the water component is in liquid state at the end of combustion (in product of combustion).

See also: Heat Content, Lower Heating Value.

High-Temperature Water Splitting

High-temperature water splitting, a longer-term technology in the early stages of development, uses high temperatures to drive a series of chemical reactions that produce hydrogen from water. The chemicals are reused within each cycle, creating a closed loop that consumes only water and produces hydrogen and oxygen. For both of the “thermo-chemical” processes described below, scientists have identified cycles appropriate to specific temperature ranges at which heat is available and are researching these systems in the laboratory.

A solar concentrator uses mirrors and a reflective or refractive lens to capture and focus sunlight to produce temperatures up to $2,000^\circ\text{C}$. Researchers have identified more than 150 chemical cycles that, in principle, could be used with heat from a solar concentrator to produce hydrogen; more than a dozen of these cycles are under active development.

One such pathway is the zinc/zinc oxide cycle, in which zinc oxide powder passes through a reactor that is heated by a solar concentrator operating at approximately $1,900^\circ\text{C}$ ($3,450^\circ\text{F}$). At this temperature, the zinc oxide dissociates to zinc and oxygen gas. The zinc is cooled, separated, and reacted with water to form hydrogen gas and solid zinc oxide. The zinc oxide can be recycled and reused to create more hydrogen.

Similarly, a nuclear reactor produces heat that can drive a series of chemical reactions to create hydrogen by splitting water and recycling the chemical constituents. The next-generation nuclear reactors under development could generate heat at temperatures of 800 to $1,000^\circ\text{C}$ ($1,470$ to $1,830^\circ\text{F}$). These temperatures are much lower than those produced by a solar concentrator, and as such, a different set of chemical reactions would be used to produce hydrogen.

The sulfur-iodine cycle is among the thermochemical cycles being investigated for this purpose. Sulfuric acid, when heated to approximately 850°C (1,560°F), decomposes to water, oxygen, and sulfur dioxide. The oxygen is removed, the sulfur dioxide and water are cooled, and the sulfur dioxide reacts with water and iodine to form sulfuric acid and hydrogen iodide. The sulfuric acid is separated and removed; the remaining hydrogen iodide is heated to 300°C (570°F), where it breaks down into hydrogen and iodine. The net result is hydrogen and oxygen, produced from water—the sulfuric acid and iodine are recycled and used to repeat the process.

See also: Hydrogen.

Homosphere

Below approximately 60 miles in altitude, the proportion of the major constituents in the atmosphere is very uniform and is known as the homosphere (the lower part of the atmosphere where the bulk gases are homogeneously mixed due to turbulent mixing or eddy diffusion), to distinguish it from the heterosphere above the approximate 60 miles of altitude, where the relative amounts of the major gaseous constituents change with height. In the homosphere there are sufficient atmospheric motions and a short enough molecular free path to maintain uniformity in composition. Above the boundary between the homosphere and the heterosphere (known as the homopause or the turbopause), the collision frequency (mean free path) of an individual molecule is sufficiently long to allow a partial separation (by gravity) of the (relatively) lighter (less dense) molecules from the heavier (more dense) constituents. Not surprisingly, the average molecular weight of the heterosphere decreases with height because the lighter (less dense) molecules dominate the composition at higher elevation.

See also: Atmosphere.

Horizontal and Vertical Axis Turbines

Both horizontal and vertical are applicable to applications such as tidal currents or river streams and are perceived as a critical element to hydrokinetic conversion concepts. Hydrokinetic energy conversion may employ either rotary turbo machinery or can use non-turbine schemes. While the former class (turbine system) encompasses various classical rotary technologies, the latter group (non-turbine system) is mostly based on various unconventional concepts. Such schemes include oscillating hydrofoil [30], vortex-induced vibration, piezo polymer conversion, and variable geometry sails.

Based on the alignment of the rotor axis with respect to water flow, three generic classes could be formed (i) horizontal axis, (ii) vertical axis, and (iii) cross flow turbines. The horizontal axis (alternately called as axial-flow) turbines have axes parallel to the fluid flow and employ propeller-type rotors. Inclined axis turbines have mostly been studied for small river energy converters. Horizontal axis turbines are common in tidal energy converters and are similar to modern-day wind turbines from concept and design point of view. Turbines with solid mooring structures require the generator unit to be placed near the riverbed or seafloor.

The cross flow turbines have rotor axes orthogonal to the water flow but parallel to the water surface (also known as floating waterwheels) are mainly drag-based devices and inherently less efficient than their lift-based counterparts. Darrieus turbines with cross flow arrangements may also fall under this category. Various arrangements under the vertical axis turbine category – in the vertical axis domain, Darrieus turbines are the most prominent options. The Gorlov turbine is another member of the vertical axis family, where the blades are of helical structure. Savonius turbines are drag-type devices, which may consist of straight or skewed blades.

Hydrokinetic turbines may also be classified based on their lift/drag properties, orientation to up/down flow, and fixed/variable (active/passive) blade pitching mechanisms. Different types of rotors may also be hybridized (such as, Darrieus–Savonius hybrid) in order to achieve certain performance features.

Hot Filtration Test

The hot filtration test (ASTM D4870) is a test to determine the stability (or instability) of a liquid fuel. An excess of sediment contained in residual fuels can cause many issues such as obstruction filters in pumps causing burner and engine systems to fail. Sediment can also accumulate on the bottom of storage tanks and cause issues with transfer pumps.

Thus, the test method is often used to examine the stability of a (conventional or alternative) fuel in which the fuel is hot-filtered to determine if solid particles exist in the fuel under the conditions of the test method.

The purpose of this test is to determine total sediment up to 0.40% m/m in residual fuel oils having a maximum viscosity of 55 centistokes at 100°C (212°F). There are some fuels that may exceed the maximum filtration time specified in this method due to factors beyond the presence of significant quantities of insoluble organic or inorganic material. The method may be used for the assessment of total sediment after regimes of fuel pretreatment designed to accelerate the aging process.

This method is performed by first starting the heating process on the filtration unit while conditioning filters. Once the filters are conditioned, they are weighed and placed on the instrument. In the next step, a beaker containing the residual fuel to be analyzed is weighed. The vacuum is then started, and the fuel oil is filtered and when the fuel has passed through the filters, they are rinsed with solvent to remove any fuel that is left so only sediment remains. The filters are then dried, cooled, and weighed. The sediment result is calculated as part of the whole sample.

See also: Bottom Sediment and Water.

Hot Gas Cleaning

When many biomass fuels are converted to gas, ash is entrained in to the gas stream. Before the gas is used, the ash must be removed to prevent slagging. Preferably, the removal should take place at the temperature of the hot gas (650 to 760°C, 1,200 to 1,400°F) so that heat is not lost during the process. The temperature at which the solids separation takes place can be lower, but it should be higher than 800 degrees F to prevent tar condensation.

Removing ash prior to combustion requires smaller solids separation equipment than would be necessary if the solids were removed after it is burned in a gas engine, gas boiler, or other energy conversion device, because the volume of gas is much greater following combustion. A smaller solids separation device is a significant advantage of gasification over direct combustion, because it can significantly reduce the costs of particulate matter emissions control.

See also: Gas Cleaning, Gas Processing, Gas Treatment.

Hot Potassium Carbonate Process

The hot potassium carbonate process has been utilized successfully for bulk removal of carbon dioxide from a number of gas mixtures. It has been used for sweetening natural gases containing both carbon dioxide and hydrogen sulfide. The process is not suitable for sweetening gas mixtures containing little or no carbon dioxide, as the potassium bisulfide should be difficult to regenerate if carbon dioxide is not present.

There are not only advantages to the use of this process, but there are also disadvantages. The advantages are: (i) it is a continuous circulating system employing an inexpensive chemical, (ii) it is an iso-thermal system in that both absorption and desorption of the acid gas are conducted at as nearly a uniform high temperature as can be obtained, thus requiring no heat exchange equipment in the fluid circulating system, and (iii) the desorption by stripping is accomplished with a smaller steam rate than required for an amine plant. On the negative side, the disadvantages are: (i) the process will not commercially reduce the hydrogen sulfide content to many pipeline specifications, (ii) the process is similar to other acid gas removal processes in that it is also prone to corrosion, and (iii) the process is also liable to problems relating to suspended solids and foaming.

The process using *potassium phosphate* is known as phosphate desulfurization, and it is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbon derivatives as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally.

Humidity

Humidity is a measure of the moisture contained in air, and the absolute humidity is a measure the amount of water in air while the relative humidity is a measure of the amount of water in air relative to the maximum amount of water the air could hold. The relative humidity increases with increasing water vapor or decreasing temperature. The dew point is the temperature at which air becomes saturated with moisture. More specifically, the absolute humidity measures the mass of water (grams) in a volume of air (cubic meters), essentially the density of water vapor (mass per volume). Thus, absolute humidity is expressed as g/m^3 (grams per cubic meter); in contrast, relative humidity is expressed as a percentage.

The absolute humidity of air varies with temperature; warm air contains more moisture than cold air, or to put it another way, warm air has higher water vapor density than an equivalent volume of cold air. Evaporation and condensation are occurring concurrently in any air mass, but one typically dominates. There is an increase in the volume of water vapor in a volume of air (absolute humidity) with increasing temperature.

Relative humidity measures the amount of moisture in air in comparison to the maximum volume of moisture the air would contain when saturated. Saturation represents the point where increasing vapor density results in condensation. Relative humidity increases if water is added to the air – adding water vapor increases the actual water vapor density.

Hybrid Poplars

Hybrid poplars are predominantly cottonwood trees and interspecific hybrids that have been selected and breed for fast growth. Sustained yields of 5 dry tons/acre/year have been documented in the north central United States and have reached 7 dry tons/acre/year on high productivity sites.

See also: Biomass, Wood.

Hydrane Process

The heart of the process is the Hydrane gasifier which is an example of a hydrogasifier which is fed with hydrogen and coal only, and the process might also be applicable to biomass feedstocks.

The hydrogen is produced in a separate unit by steam/oxygen gasification of unreacted char from the hydrogasifier. The Hydrane process was investigated by the U.S. Bureau of Mines (now incorporated in the Department of Energy) from 1955 up to the mid-1970s. The first reactor is a pretreatment stage in which the agglomerating properties of the coal are destroyed. Most American coals have been found to exhibit severe caking properties in high pressure hydrogen atmospheres at elevated temperatures, and coal agglomeration with concomitant plugging of reactors has consequently proved to be a major problem in the development of hydrogasifier units.

This problem is overcome in the Hydrane gasifier by partial gasification of the coal in the dilute-phase stage, where the particles react out of contact with each other. Wall temperatures have to be maintained above approximately $750^\circ C$ ($1,380^\circ F$) to prevent the coal particles from adhering to them. The gas/coal flow in the dilute-phase reactor allows devolatilization products to be cracked, and leaves the product gas relatively free of tars and oils.

In the Hydrane process, more than 90% of the methane produced is generated within the gasifier, thus minimizing the necessity for subsequent catalytic methanation processes. In the process, coal enters the gasifier and falls through a countercurrently flowing stream of hot gases rising from the second stage fluidized bed, therefore allowing

agglomerating coal to be hydrogasified (any agglomerating properties are usually destroyed during the preheating step). The preheated solids then enter the second zone (consisting of a bed fluidized by hydrogen) which permits maximum coal conversion without cracking the methane product to carbon.

The product gas requires purification and methanation so that the final product meets pipeline specifications. The char from the gasifier may be either completely consumed in synthesis gas production, or it may be used for power production.

Hydrocarbon and Carbon Monoxide Controls

The emission of hydrocarbon derivatives and carbon monoxide will be caused by the incomplete combustion of the fuel for the boilers, furnaces, heaters, and diesel equipment used in oil shale plants. The control of external combustion sources such as boilers is primarily through proper design, operation, and maintenance.

Treating the flue gas from combustion sources for particulate or sulfur dioxide will also reduce hydrocarbon and carbon monoxide emissions. Other emissions of hydrocarbon derivatives will be caused by preheating raw shale prior to retorting and by storing crude shale oil and refined products.

Storage tank emissions can be minimized by using floating-roof tanks, which can accommodate higher vapor pressures than cone-roof tanks without the need for venting.

Hydrocarbon Fuels

Hydrocarbon derivatives, as such, are not usually produced from crops, there being insufficient amount of the hydrocarbon derivatives present in the plant tissue to make the process economical. However, biodiesel is produced from crops thereby offering an excellent renewable fuel for diesel engines.

The distillable oil obtained from the fast pyrolysis of biomass has high oxygen content. Ketone derivatives and aldehyde derivatives, carboxylic acid derivatives, ester derivatives, aliphatic and aromatic alcohol derivatives, and ether derivative have been detected in significant quantities. Because of the reactivity of oxygenated groups, the main problems of the oil are instability. The hydrodeoxygenation (HDO) of bio-oil in the presence of a cobalt molybdate catalyst was studied (Zhang et al., 2003), which is a most important route for upgrading the oil.

The reaction has strong analogies with typical refinery processes, such as the hydrodesulfurization and hydrodenitrogenation processes. In general, most of the hydrodeoxygenation studies have been performed using existing hydrodesulfurization catalysts (NiMo and CoMo on suitable carriers). However, these types of catalyst need activation using a suitable sulfur source and this is a major drawback when using low-to-no sulfur resources.

Hydrocarbon Gases – Physical Constants

The number of carbon atoms in a member of the paraffin series determines whether the hydrocarbon will exist as a gas, a liquid, or a solid under standard conditions of temperature and pressure (STP' 60°F, 760 mm Hg) (Table H-4). Methane (CH_4) is a gas under all naturally occurring temperature and pressure conditions. Ethane (C_2H_6), propane (C_3H_8), butane (C_4H_{10}), and its isomers are gaseous under standard surface conditions (Table) but may exist in either gaseous or liquid phase under the elevated temperature and pressure conditions found in subsurface reservoirs. On the other hand, members of the paraffin series with between 5 and 17 carbon atoms in their molecular structures (such as pentane, C_5H_{12} , hexane, C_6H_{14} , heptane, C_7H_{16} , octane, C_8H_{18}) are liquid under standard surface conditions and most temperature and pressure conditions encountered in subsurface reservoirs. Members of the paraffin series

with more than 17 carbon atoms are solid under most naturally occurring temperatures and pressures and when isolated from crude oil form the mixture known as paraffin wax.

Table H-4 Properties of gaseous (C_1 - C_4) paraffin hydrocarbons.

	Molecular	Boiling point	Density at 60°F	Density
Gas	weight	1 atm, °C (OF)	g/liter	Relative to air = 1
Methane	16.043	-161.5 (-258.7)	0.6786	0.5547
Ethylene	28.054	-103.7 (-154.7)	1.1949	0.9768
Ethane	30.068	-88.6 (-127.5)	1.2795	1.046
Propylene	42.081	-47.7 (-53.9)	1.8052	1.4757
Propane	44.097	-42.1 (-43.8)	1.8917	1.5464
1,2- Butadiene	54.088	10.9 (51.6)	2.3451	1.9172
1,3-Butadiene	54.088	-4.4 (24.1)	2.3491	1.9203
1-Butene	56.108	-6.3 (20.7)	2.4442	1.9981
cis-2-Butene	56.108	3.7 (38.7)	2.4543	2.0063
trans-2-Butene	56.108	0.9 (33.6)	2.4543	2.0063
iso-Butene	56.104	-6.9 (19.6)	2.4442	1.9981
n-Butane	58.124	-5.4 (31.1)	2.532	2.0698
iso-Butane	58.124	-11.7 (10.9)	2.5268	2.0656

Hydrocarbons

Hydrocarbons (hydrocarbon derivatives) are organic compounds which are composed of carbon and hydrogen only. The insertion of any non-carbon or non-hydrogen element in the molecule disqualifies that molecule from being a hydrocarbon.

The three simplest families of hydrocarbons are known as the alkanes, alkenes, and alkynes. Alkanes have the formula $C_n H_{2n+2}$ while alkenes have a double bond ($>C=C<$) in the molecule with the general formula $C_n H_{2n}$ and alkynes have a triple bond in the structure ($-C\equiv C-$) with the general formula $C_n H_{2n-2}$. The classifications for hydrocarbon are (i) saturated hydrocarbons, (ii) unsaturated hydrocarbons, and (iii) aromatic hydrocarbons.

Saturated hydrocarbons (alkanes) are the simplest of the hydrocarbon types and are composed entirely of single bonds that are saturated with hydrogen. The most general form of saturated hydrocarbons is $C_n H_{2n+2(1-r)}$, where r is the number of rings. Those with exactly one ring are the cycloalkanes. Unsaturated hydrocarbons (alkenes) have one or more double or triple bonds between carbon atoms. Those with one double bond have the formula $C_n H_{2n}$ (assuming they have a non-cyclic structure). Aromatic hydrocarbon derivatives (the arenes) hydrocarbons that have at least one aromatic ring in the molecule. The term aliphatic refers to non-aromatic hydrocarbons. Saturated aliphatic hydrocarbons are sometimes referred to as 'paraffins'. Aliphatic hydrocarbons containing a double bond between carbon atoms are sometimes referred to as olefins.

Hydrocarbon derivatives are also prevalent in nature. For example, there are certain species of flowering plants belonging to different families which convert a substantial amount of photosynthetic products into latex. The latex of such plants contains liquid hydrocarbon derivatives of high molecular weight (10,000). These hydrocarbon derivatives can be converted into high grade transportation fuel (i.e., crude oil). Therefore, hydrocarbon producing plants are called crude oil plants or petroplants and their crop as petrocrop. Natural gas is also one of the products obtained from hydrocarbon derivatives. Thus, crude oil plants can be a renewable resource for obtaining crude oil to be used in diesel engines. Normally, some of the latex-producing plants of families Euphorbiaceae, Apocynaceae, Asclepiadaceae,

Sapotaceae, Moraceae, Dipterocarpaceae, etc. are petroplants. Similarly, sunflower (family Compositae) and *Hardwickia pinnata* (family Leguminosae) are also petroplants. Some algae also produce hydrocarbon derivatives.

Different species of *Euphorbia* of family Euphorbiaceae serve as the petroplants that have the potential to be a renewable substitute for the conventional crude oil sources. The latex of *Euphorbia lathyris* contains fairly high percentage of terpenoids. These can be converted into high grade transportation fuel. Similarly, the carbohydrates (hexoses) from such plants can be used for ethanol formation.

Sugarcane (*Saccharum officinarum* - family Gramineae) is the main source of raw material for sugar industry. The wastes from sugar industry include bagasse, molasses, and press mud. After extracting the cane juice for sugar production, the cellulosic fibrous residue that remains is called bagasse. It is used as the raw material (biomass) and processed variously for the production of fuel, alcohols, single cell protein as well as in paper mills. Molasses is an important by-product of sugar mills and contains 50-55% fermentable sugars. One ton of molasses can produce approximately 280 liters of ethanol. Molasses is used for the production of animal feed, liquid fuel, and alcoholic beverages.

Sugar beet (*Beta vulgaris*, family-Chenopodiaceae) is yet another plant which contains a high percentage of sugars stored in fleshy storage roots. It is also an important source for production of sugar as well as ethanol.

Raising crops like sugarcane, sugar beet, tapioca, potato, maize, etc., purely for production of ethanol is described as energy cropping, and the crops are called energy crops. Cultivation of plants (trees) for obtaining fuel/fire wood is described as energy plantation. Other plants, such as Euphorbiaceae plants like *Euphorbia lathyris*, milkweed (*Asclepias speciosa*) and the tree legume *Copaifera multijuga*, produce hydrocarbon derivatives which can be converted into and used as diesel. In addition, some freshwater and marine algae are also known to accumulate hydrocarbon derivatives. Some algae like Chlamydomonas and anaerobic bacteria like Clostridium produce hydrogen gas, which can be used as a pollution free fuel. Long-term research efforts are needed to develop these organisms as sources of bioenergy.

The euphorbeans and milkweeds can be grown in relatively dry environments on lands not suited for crop production; this makes them highly attractive sources of biofuels. The Euphorbias are relatives of plants used to produce rubber; they produce a latex, which has approximately 30% hydrocarbon derivatives emulsified in water.

However, hydrocarbon derivatives, as such, are not usually produced from crops, there being an insufficient amount of the hydrocarbon derivatives present in the plant tissue to make the process economical. However, biodiesel is produced from crops thereby offering an excellent renewable fuel for diesel engines.

There are certain species of flowering plants belonging to different families which convert a substantial amount of photosynthetic products into latex. The latex of such plants contains liquid hydrocarbon derivatives of high molecular weight (10,000). These hydrocarbon derivatives can be converted into high-grade transportation fuel (i.e., petroleum). Therefore, hydrocarbon-producing plants are called petroleum plants or petroplants and their crop as petrocrop. Natural gas is also one of the products obtained from hydrocarbon derivatives. Thus, petroleum plants can be an alternative source for obtaining petroleum to be used in diesel engines. Normally, some of the latex-producing plants of families Euphorbiaceae, Apocynaceae, Asclepiadaceae, Sapotaceae, Moraceae, and Dipterocarpaceae are petroplants. Similarly, sunflower (family Compositae) and *Hardwickia pinnata* (family Leguminosae) are also petroplants. Some algae also produce hydrocarbon derivatives.

Different species of *Euphorbia* of family Euphorbiaceae serve as the petroplants that have the potential to be a renewable substitute for the conventional petroleum sources. Latex of *Euphorbia lathyris* contains a fairly high percentage of terpenoids. These can be converted into high-grade transportation fuel. Similarly, the carbohydrates (hexoses) from such plants can be used for ethanol formation.

Sugarcane (*Saccharum officinarum* - family Gramineae) is the main source of raw material for sugar industry. The wastes from sugar industry include bagasse, molasses, and press mud. Hydrocracking

Hydrocracking (hydroconversion) is a catalytic high-pressure high-temperature process for the conversion of a variety of feedstocks (including bio-oil) in the presence of fresh and recycled hydrogen; carbon-carbon bonds are cleaved in addition to the removal of heteroatom species. Like hydrotreating, hydrocracking also falls under the general umbrella of hydroprocessing. The outcome is the conversion of a variety of feedstocks to a range of products, and units to accomplish this goal can be found at various points in a refinery.

Hydrocracking is a more recent process development compared to the older thermal cracking, visbreaking, and coking. In fact, the use of hydrogen in thermal processes is perhaps the single most significant advance in refining technology during the twentieth century and the ability of refiners to cope with the renewed trend toward distillate production from heavier feedstocks with low atomic hydrogen/carbon ratios has created a renewed interest in hydrocracking. Without the required conversion units, heavier crude oils produce in lower yields of naphtha and middle distillate. To maintain current gasoline and middle distillate production levels, additional conversion capacity is required because of the differential in the amount of distillates produced from conventional (low-density or conventional) crude oil and the distillate products produced from heavier crude oil.

The concept of hydrocracking allows the refiner to produce products having a lower molecular weight with higher hydrogen content and a lower yield of coke. In summary, hydrocracking facilities add flexibility to refinery processing and to the product slate. Hydrocracking is more severe than hydrotreating there being the intent, in hydrocracking processes, to convert the feedstock to lower-boiling products rather than to treat the feedstock for heteroatom and metals removal only.

Hydrocracking is an extremely versatile process that can be utilized in many different ways, and one of the advantages of hydrocracking is its ability to break down high-boiling aromatic stocks produced by catalytic cracking or coking (Figure H-1).

Figure H-1 Single-stage and double-stage hydrocracking.

To take full advantage of hydrocracking, the process must be integrated in the refinery with other process units. In gasoline production, for example, the hydrocracker product must be further processed in a catalytic reformer as it has a high naphthene content and relatively low octane number. The high naphthene content makes the hydrocracker gasoline an excellent feed for catalytic reforming, and good yields of high-octane-number gasoline can be obtained.

If high-molecular-weight petroleum fractions are pyrolyzed, that is, if no hydrogenation occurs, progressive cracking and condensation reactions generally lead to the final products. These products are usually (i) gaseous and low-boiling liquid compounds of high hydrogen content, and/or (ii) liquid material of intermediate molecular weight with a hydrogen-carbon atomic ratio differing more or less from that of the original feedstock, depending on the method of operation, and/or (iii) material of high molecular weight, such as coke, possessing a lower hydrogen-carbon atomic ratio than the starting material.

Highly aromatic or refractory recycle stocks or gas oils that contain varying proportions of highly condensed aromatic structures (for example, naphthalene and phenanthrene) usually crack, in the absence of hydrogen, to yield intractable residues and coke.

An essential difference between pyrolysis (thermal decomposition, usually the absence of any added agent) and hydrogenolysis (thermal decomposition in the presence of hydrogen and a catalyst or a hydrogen-donating solvent) of petroleum is that in pyrolysis, a certain amount of polymerized heavier products, like cracked residuum and coke, is always formed along with the low-boiling products, such as gas and naphtha (a gasoline precursor). During hydrogenolysis (destructive hydrogenation), polymerization may be partly or even entirely prevented so that only low-boiling products are formed. The prevention of coke formation usually results in an increased distillate (e.g., gasoline) yield. Depending on the feedstock being processed and the type of plant design employed (single-stage or two-stage), flexibility can be provided to vary product distribution.

Though several technologies exist to upgrade high-boiling feedstocks, selection of the optimum process units is very much dependent on the requirements and goals of each refinery, with the market pull being the prime motivator. Furthermore, processing options systems to dig deeper into the barrel by converting more of the higher boiling materials to distillable products should not only be cost-effective and reliable, but also flexible.

Hydrocracking adds that flexibility and offers the refiner a process that can handle varying feeds and operate under diverse process conditions. Utilizing different types of catalysts can modify the product slate produced. Reactor design and the number of processing stages play a role in this flexibility. Finally, in relation to the conversion measures for upgrading processes. Such measures are necessary for any conversion process but more particularly for hydrocracking processes where hydrogen management is an integral, and essential, part of process design.

The objective of any upgrading process is to convert high-boiling feedstocks into marketable products by reducing their heteroatom (nitrogen, oxygen, and sulfur) and metal contents, modifying the structures of the asphaltene constituents (reducing coke precursors), and converting the high-molecular-weight polar species large molecules into lower-molecular-weight and lower-boiling hydrocarbon products. Upgrading processes are evaluated on the basis of liquid yield (i.e., naphtha, distillate and gas oil), heteroatom removal efficiency, feedstock conversion (FC), carbon mobilization (CM), and hydrogen utilization (HU), along with other process characteristics. Definition of FC, CM, and HU are:

$$FC = (\text{Feedstock}_{\text{IN}} - \text{Feedstock}_{\text{OUT}}) / \text{Feedstock}_{\text{IN}} \times 100$$

$$CM = \text{Carbon}_{\text{LIQUIDS}} / \text{Carbon}_{\text{FEEDSTOCK}} \times 100$$

$$HU = \text{Hydrogen}_{\text{LIQUIDS}} / \text{Hydrogen}_{\text{FEEDSTOCK}} \times 100$$

High carbon mobilization (CM <100%) and high hydrogen utilization (HU) correspond to high feedstock conversion (RC) processes involving hydrogen addition such as hydrocracking. Since hydrogen is added, hydrogen utilization can be greater than 100%. These tasks can be achieved by using thermal and/or catalytic processes. Low carbon mobilization and low hydrogen utilization correspond to low feedstock conversion such as coking (carbon rejection) processes. Maximum efficiency from an upgrading process can be obtained by maximizing the liquid yield

and its quality by minimizing the gas (C_1 - C_4) yield, simultaneously. Under these operating conditions the hydrogen consumption would be the most efficient, i.e., hydrogen is consumed to increase the liquid yield and its quality. Several process optimization models can be formulated if the reaction kinetics is known.

Hydrocracking generates air emissions through process heater flue gas, vents, and fugitive emissions. Unlike fluid catalytic cracking catalysts, hydrocracking catalysts are usually regenerated off-site after months or years of operations, and little or no emissions or dust are generated. However, the use of heavy crude oil as feedstock to the unit can change this balance.

Hydrocracking produces less sour wastewater than catalytic cracking. Hydrocracking, like catalytic cracking, produces sour wastewater at the fractionator. These processes include processing in a separator (API separator, corrugated plate interceptor) that creates a sludge. Physical or chemical methods are then used to separate the remaining emulsified oils from the wastewater. Treated wastewater may be discharged to public wastewater treatment, to a refinery secondary treatment plant for ultimate discharge to public wastewater treatment, or may be recycled and used as process water. The separation process permits recovery of usable oil, and also creates a sludge that may be recycled or treated as a hazardous waste.

In addition, oily sludge from the wastewater treatment facility that results from treating sour wastewaters may be hazardous wastes (unless they are recycled in the refining process). These include API separator sludge, primary treatment sludge, sludge from various gravitational separation units, and float from dissolved air flotation units.

Hydrocracking Catalysts

Hydrocracking catalysts typically contain separate hydrogenation and cracking functions. Palladium sulfide and promoted group VI sulfides (nickel molybdenum or nickel tungsten) provide the hydrogenation function. These active compositions saturate aromatics in the feed, saturate olefins formed in the cracking, and protect the catalysts from poisoning by coke. Zeolites or amorphous silica-alumina provide the cracking functions. The zeolites are usually type Y (faujasite), ion exchanged to replace sodium with hydrogen and make up 25 to 50% of the catalysts. Pentasils (silicalite or ZSM-5) may be included in dewaxing catalysts.

Hydrocracking catalysts, such as nickel (5% by weight) on silica-alumina, work best on feedstocks that have been hydrofined to low nitrogen and sulfur levels. The nickel catalyst then operates well at 350 to 370°C (660 to 700°F) and a pressure of approximately 1,500 psi to give good conversion of feed to lower-boiling liquid fractions with minimum saturation of single-ring aromatics and a high iso-paraffin-to-n-paraffin ratio in the lower- molecular-weight paraffins.

The poisoning effect of nitrogen can be offset to a certain degree by operation at a higher temperature. However, the higher temperature tends to increase the production of material in the methane (CH_4) to butane (C_4H_{10}) range and decrease the operating stability of the catalyst so that it requires more frequent regeneration. Catalysts containing platinum or palladium (approximately 0.5% wet) on a zeolite base appear to be somewhat less sensitive to nitrogen than are nickel catalysts, and successful operation has been achieved with feedstocks containing 40 ppm nitrogen. This catalyst is also more tolerant of sulfur in the feed, which acts as a temporary poison, the catalyst recovering its activity when the sulfur content of the feed is reduced.

On such catalysts as nickel or tungsten sulfide on silica-alumina, isomerization does not appear to play any part in the reaction, as uncracked normal paraffins from the feedstock tend to retain their normal structure. Extensive splitting produces large amounts of low-molecular-weight (C_3 - C_6) paraffins, and it appears that a primary reaction of paraffins is catalytic cracking followed by hydrogenation to form iso-paraffins. With catalysts of higher hydrogenation activity, such as platinum on silica-alumina, direct isomerization occurs. The product distribution is also different, and the ratio of low- to intermediate-molecular-weight paraffins in the breakdown product is reduced.

In addition to the chemical nature of the catalyst, the physical structure of the catalyst is also important in determining the hydrogenation and cracking capabilities, particularly for high-boiling feedstocks. When gas oils and residua are used, the feedstock is present as liquids under the conditions of the reaction. Additional feedstock and

the hydrogen must diffuse through this liquid before reaction can take place at the interior surfaces of the catalyst particle.

At high temperatures, the reaction rates can be much higher than diffusion rates and concentration gradients can develop within the catalyst particle. Therefore, the choice of catalyst porosity is an important parameter. When feedstocks are to be hydrocracked to liquefied petroleum gas and gasoline, pore diffusion effects are usually absent. High surface area (approximately 300 m²/g) and low-to-moderate porosity. With reactions involving high-molecular-weight feedstocks, pore diffusion can exert a large influence, and catalysts with pore diameters greater than 80 Å are necessary for more efficient conversion.

Precious metal catalysts, particularly catalysts incorporating platinum or platinum and palladium, are used in the latter stages of deep-desulfurization process. They have excellent performance in hydrogenation of monocyclic aromatic hydrocarbon derivatives and are likely to become more and more important in the years ahead, and refiners seek to hydrocrack higher amounts of the high-boiling feedstocks. Current efforts are seeking to produce such catalysts with increased hydrogenation activity as well as resistance to sulfur and nitrogen poisoning while balancing these characteristics. In addition, work is being done to assign appropriate cracking activity to match specific applications using inorganic (composite) oxides, such as amorphous alumina, silica alumina, or crystalline silica alumina, as carriers and optimization of the amount of the precious metals and highly-dispersed metal impregnation methods.

The cobalt-molybdenum, nickel-molybdenum, and precious metal catalysts are also available for use in deep desulfurization and aromatics hydrogenation. These catalysts should be helpful in producing diesel fuel with a sulfur content of 50 ppm or less only by substituting catalysts. The bimetallic catalyst in the reaction mix promotes (i) formation of an olefin, (ii) hydrogenation of fragments, and (iii) prevents condensation reactions which lead to catalyst fouling.

Hydrocracking Chemistry

Hydrogen is consumed in all hydrocracking reactions. Carbon-carbon bonds in feedstock constituents are broken and the fragments hydrogenated to form lower-molecular-weight products. Polycyclic aromatics are partially saturated and ring opening in one or more places follows – at least one ring is usually retained. Dual function catalysts containing both acid activity and hydrogenation-dehydrogenation activity are required.

Hydrocracking reactions are initiated by partial dehydrogenation over the metallic components in the catalyst to form an olefin; of course, it is in a low concentration and is rapidly adsorbed on an acid site and converted to carbonium ion cracks (usually in the β -position) to form two fragments that may undergo further cracking, but at some critical molecular weight, they become hydrogenated, and desorbed from the catalyst and constitute final product.

The chemistry of hydrocracking is basically similar to that of catalytic cracking, but with concurrent hydrogenation. The catalyst assists in the production of carbonium ions via olefin intermediates, and these intermediates are quickly hydrogenated under the high-hydrogen partial pressures employed in hydrocracking. The rapid hydrogenation prevents adsorption of olefins on the catalyst and, hence, prevents their subsequent dehydrogenation, which ultimately leads to coke formation so that long on-stream times can be obtained without the necessity of catalyst regeneration.

One of the most important reactions in hydrocracking is the partial hydrogenation of polycyclic aromatics followed by rupture of the saturated rings to form substituted monocyclic aromatics. The side chains may then be split off to give iso-paraffins. It is desirable to avoid excessive hydrogenation activity of the catalyst so that the monocyclic aromatics become hydrogenated to naphthenes; furthermore, repeated hydrogenation leads to loss in octane number, which increases the catalytic reforming required to process the hydrocracked naphtha.

Side chains of three or four carbon atoms are easily removed from an aromatic ring during catalytic cracking, but the reaction of aromatic rings with shorter side chains appears to be quite different. For example, hydrocracking single-ring aromatics containing four or more methyl groups produces largely iso-butane and benzene. It may be that successive isomerization of the feed molecule adsorbed on the catalyst occurs until a four-carbon side chain is formed, which then breaks off to yield iso-butane and benzene. Overall, coke formation is low in hydrocracking

since the secondary reactions and the formation of the precursors to coke are suppressed as the hydrogen pressure is increased.

It is the physical and chemical composition of a feedstock that plays a large part not only in determining the nature of the products that arise from refining operations but also in determining the precise manner by which a particular feedstock should be processed. Furthermore, it is apparent that the conversion of heavy crude oils and residua requires new lines of thought to develop suitable processing scenarios. Indeed, the use of thermal (carbon rejection) processes and of hydrothermal (hydrogen addition) processes, which were inherent in the refineries designed to process low-boiling feedstocks, has been a particular cause for concern. This has brought about the evolution of processing schemes that accommodate the heavier feedstocks. As a point of reference, an example of the former option is the delayed coking process in which the feedstock is converted to overhead with the concurrent deposition of coke, for example that used by Suncor, Inc., at their oil sands plant.

Hydrocracking Processes

There are three basic flow schemes for hydrocracking processes which are (i) single-stage, (ii) two-stage, and (iii) series flow, although there are many modifications of each but pertinent features (Figure H-1). The choice of flow scheme depends upon the feedstock, the desired products, and the flexibility that is chosen for the process.

In the single-stage system, fresh feedstock along with recycled hydrogen is heated to the desired reaction temperature, and then contacted with catalyst in the reactor. Hydrocracking reactions are exothermic, and to control temperatures in the desired range, conversion per pass can be limited or cooling with quench recycle gas can be used. The reactor effluent is heat-exchanged and passed to a high-pressure separator. Hydrogen and high pressure separator liquid are flashed into a low-pressure drum where most of the dissolved gases are removed from the normal liquid product. The flash drum liquid is fed to a fractionator for separation into the desired products. Fractionator bottoms boiling range of the products can be recycled for complete conversion.

In the two-stage system, there are two complete reactor stages, each containing a charge pump, recycle compressor, heat exchangers, heater, reactor, cooler, and high-pressure fractionator. The first stages are separated by the stripper or fractionator. The first-stage reactor decomposes nitrogen and sulfur compounds, saturates olefins, and partially saturates polycyclic aromatics. The stripper or fractionator removes H₂S, NH₃, and other low-boiling gases, leaving a mixture of paraffins, naphthenes, and aromatics essentially free from impurities. The second stage processes the cleaned feedstock and converts it into the desired boiling range products. This system is the most versatile of the two-reactor schemes as regards variety of charge stocks and products which can be accommodated. A large number of such units are on stream for processing feedstocks such as high-boiling as vacuum gas oil and propane-deasphalted gas oils to produce naphtha, kerosene, and distillates.

The series-flow two-reactor system is similar to the one-reactor system except that there are two reactors in series, as shown, each containing a different catalyst. The first reactor performs the same function as the first reactor in the two-stage scheme. The second reactor carries out the hydrocracking reactions in the presence of hydrogen sulfide and ammonia. This scheme has the advantage of being more economical to build and operate in some instances.

The reactor effluent is cooled through a variety of heat exchangers including the feed-effluent exchanger and one or more air coolers. De-aerated condensate is injected into the first-stage reactor effluent before the final air cooler in order to remove ammonia and some of the hydrogen sulfide. This prevents solid ammonium disulfide from depositing in the system. A body of expertise in the field of materials selection for hydrocracker cooling trains is quite important for proper design.

The reactor effluent leaving the air cooler is separated into hydrogen-rich recycle gas, a sour water stream, and a hydrocarbon liquid stream in the high-pressure separator. The sour water effluent stream is often then sent to a plant for ammonia recovery and for purification so water can be recycled back to the hydrocracker. The hydrocarbon rich stream is pressure reduced and fed to the distillation section after low-boiling products are flashed off in a low-pressure separator. The hydrogen-rich gas stream from the high-pressure separator is recycled back to the reactor feed by using a recycle compressor. Sometimes with sour feeds, the first-stage recycle gas is scrubbed with an amine system to remove hydrogen. If the feed sulfur level is high, this option can improve the performance of the catalyst and result in less costly materials of construction.

Overall, a single-stage once-through (SSOT) unit resembles the first stage of the two-stage plant. This type of hydrocracker usually requires the least capital investment. The feedstock is not completely converted to low-boiling products. For this application, the refiner must have a demand for highly refined heavy crude oil. In many refining situations, such an oil product can be used as lube oil plant feed or as FCC plant feed or in low sulfur oil blends or as ethylene plant feed. It also lends itself to stepwise construction of a future two-stage hydrocracker for full feed conversion.

A single-stage recycle (SSREC) unit converts heavy crude oil completely into low-boiling products with a flow scheme resembling the second stage of the two-stage plant. Such a unit maximizes the yield of naphtha, jet fuel, or diesel depending on the recycle cut point used in the distillation section. This type of unit is more economical than the more complex two-stage unit when plant design capacity is less than approximately 10,000 to 15,000 bbl/day. Commercial SSRFC plants have operated to produce low pour point diesel fuel from waxy Middle East vacuum gas oils. Recent emphasis has been placed on the upgrading of low-boiling gas oils into jet fuels.

Building on the theme of one- or two-stage hydrocracking, the once-through partial conversion (OTPC) concept evolved. This concept offers the means to convert high-boiling vacuum gas oil feed into high quality gasoline, jet fuel, and diesel products by a partial conversion operation. The advantage is lower initial capital investment and also lower utilities consumption than a plant designed for total conversion. Because total conversion of the higher molecular weight compounds in the feedstock is not required, once-through hydrocracking can be carried out at lower temperatures and in most cases at lower hydrogen partial pressures than in recycle hydrocracking, where total conversion of the feedstock is normally an objective.

One disadvantage of once-through hydrocracking compared to a recycle operation is a somewhat reduced flexibility for varying the ratio of gasoline to middle distillate that is produced. A greater quantity of naphtha can be produced by increasing conversion, and production of jet fuel plus diesel can also be increased. But selectivity for higher boiling products is also a function of conversion. Selectivity decreases as once-through conversion increases. If conversion is increased too much, the yield of desired product will decrease, accompanied by an increase in gas production and the production of other low-boiling products. Higher yields of naphtha or kerosene are possible from a recycle operation rather than from a once-through operation.

Hydrodenitrogenation

Many types of biomass contain alkaloids and other forms of nitrogen-containing species. The nitrogen, which can be a serious disadvantage in fuels, must be removed from the bio-oil, and this is achieved by a process known as hydrodenitrogenation which is the removal of nitrogen by hydrotreating.

Hydrodenitrogenation is more difficult to accomplish than hydrodesulfurization, but the relatively smaller amounts of nitrogen-containing compounds in conventional crude oil made this of little concern to refiners. However, the trend to heavier feedstocks in refinery operations, which are richer in nitrogen than the conventional feedstocks, has increased the awareness of refiners to the presence of nitrogen compounds in crude feedstocks. For the most part, however, hydrodesulfurization catalyst technology has been used to accomplish hydrodenitrogenation although such catalysts are not ideally suited to nitrogen removal. Limitations of hydrodesulfurization catalysts when applied to hydrodenitrogenation have been recognized, and there are reports of attempts to manufacture catalysts more specific to nitrogen removal.

See also: Hydrodesulfurization.

Hydrodesulfurization

Hydrodesulfurization is the removal of sulfur from feedstocks, such as shale oil, by the use of hydrogen and a catalyst.

The reactor design commonly used in hydrodesulfurization of distillates is the fixed-bed reactor design in which the feedstock enters at the top of the reactor and the product leaves at the bottom of the reactor.

The catalyst remains in a stationary position (fixed-bed) with hydrogen and petroleum feedstock passing in a downflow direction through the catalyst bed. The hydrodesulfurization reaction is exothermic, and the temperature rises from the inlet to the outlet of each catalyst bed. With a high hydrogen consumption and subsequent large temperature rise, the reaction mixture can be quenched with cold recycled gas at intermediate points in the reactor system. This is achieved by dividing the catalyst charge into a series of catalyst beds, and the effluent from each catalyst bed is quenched to the inlet temperature of the next catalyst bed.

The extent of desulfurization is controlled by raising the inlet temperature to each catalyst bed to maintain constant catalyst activity over the course of the process. Fixed-bed reactors are mathematically modeled as plug-flow reactors with little back mixing in the catalyst beds. The first catalyst bed is poisoned with vanadium and nickel at the inlet to the bed and may be a cheaper catalyst (guard bed). As the catalyst is poisoned in the front of the bed, the temperature exotherm moves down the bed and the activity of the entire catalyst charge declines thus requiring a raise in the reactor temperature over the course of the process sequence. After catalyst regeneration, the reactors are opened and inspected, and the high metal content catalyst layer at the inlet to the first bed may be discarded and replaced with fresh catalyst. The catalyst loses activity after a series of regenerations and, consequently, after a series of regenerations, it is necessary to replace the complete catalyst charge. In the case of feedstocks with a high metal content, it is often necessary to replace the entire catalyst charge rather than to regenerate it. This is due to the fact that the metal contaminants cannot be removed by economical means during rapid regeneration, and the metals have been reported to interfere with the combustion of carbon and sulfur, catalyzing the conversion of sulfur dioxide (SO_2) to sulfate (SO_4^{2-}) that has a permanent poisoning effect on the catalyst.

Fixed-bed hydrodesulfurization units are generally used for distillate hydrodesulfurization and may also be used for residuum hydrodesulfurization but require special precautions in processing. The residuum must undergo two-stage electrostatic desalting so that salt deposits do not plug the inlet to the first catalyst bed, and the residuum must be low in vanadium and nickel content to avoid plugging the beds with metal deposits. Hence, the need for a guard bed in residuum hydrodesulfurization reactors.

During the operation of a fixed-bed reactor, contaminants entering with fresh feed are filtered out and fill the voids between catalyst particles in the bed. The buildup of contaminants in the bed can result in the channeling of reactants through the bed and reducing the hydrodesulfurization efficiency. As the flow pattern becomes distorted or restricted, the pressure drop throughout the catalyst bed increases. If the pressure drop becomes high enough, physical damage to the reactor internals can result. When high-pressure drops are observed throughout any portion of the reactor, the unit is shut down and the catalyst bed is skimmed and refilled.

With fixed-bed reactors, a balance must be reached between reaction rate and pressure drop across the catalyst bed. As catalyst particle size is decreased, the desulfurization reaction rate increases but so does the pressure drop across the catalyst bed. Expanded-bed reactors do not have this limitation, and small 1/32 inch (0.8 mm) extrudate catalysts or fine catalysts may be used without increasing the pressure drop.

Hydrodesulfurization Catalysts

Hydrodesulfurization catalysts consist of metals impregnated on a porous alumina support. Almost all of the surface area is found in the pores of the alumina (200 to 300 m^2/g), and the metals are dispersed in a thin layer over the entire alumina surface within the pores. This type of catalyst does display a huge catalytic surface for a small weight of catalyst. Cobalt (Co), molybdenum (Mo), and nickel (Ni) are the most commonly used metals for desulfurization catalysts. The catalysts are manufactured with the metals in an oxide state. In the active form, they are in the sulfide state, which is obtained by sulfiding the catalyst either prior to use or with the feed during actual use. Any catalyst

that exhibits hydrogenation activity will catalyze hydrodesulfurization to some extent. However, the Group VIB metals (chromium, molybdenum, and tungsten) are particularly active for desulfurization, especially when promoted with metals from the iron group (iron, cobalt, and nickel).

Hydroelectric Dams

Dams have existed for thousands of years. The oldest known dam, the Sadd el-Kafara (Arabic for “Dam of the Pagans”), was constructed over 4,500 years ago twenty miles south of Cairo, Egypt. The 348-foot wide, 37-foot high dam was constructed to create a reservoir in the Wadi el-Garawi. The dam was built with limestone blocks, set in rows of steps approximately eleven inches high. It appears that the dam was supposed to be used to create a reservoir that would supply drinking water for people and animals working in a nearby quarry. Scientists and archaeologists believe that the Sadd el-Kafara failed after only a few years of use because there is no evidence of siltation at the remains of the dam. When water flows into the reservoir created by a dam, the silt—sand and other debris carried with the stream—is allowed to settle, rather than be borne further downstream by the force of the flow of a stream or river. In the still water behind a dam, this sediment is deposited on the bottom of the reservoir.

The earliest dams were built for utilitarian purposes, to create reservoirs for drinking supplies—as in the Sadd el-Kafara—or to prevent flooding or for irrigation purposes. Early dams were even used to create lakes for recreational purposes. In the middle of the first century, the Roman emperor, Nero, constructed three dams to create three lakes to add to the aesthetic beauty of his villa.

Currently, a variety of dam structures are utilized which can be classified as either (i) embankment dams or (ii) concrete dams. Embankment dams are constructed with locally available natural resources. There are several different types of embankment dams, including earth dams—which are constructed primarily of compacted earth; tailings dams—constructed from mine wastes; and rockfill dams—which are constructed with dumped or compacted rock. The shape of these dams is usually dependent on the natural settling angle of the materials used to build them. Concrete, bitumen, or clay is often used to prevent water from seeping through the dam. This can be in the form of a thin layer of concrete or bitumen facing which acts as a seal, or in the form of a central core wall of clay or other fine materials constructed within the dam, allowing water to penetrate the upstream side of the structure, but preventing it from moving beyond the clay core.

Concrete dams are more permanent structures than embankment dams. Concrete dams can be categorized as gravity, arch, or buttress. Because concrete is a fairly expensive material, different construction techniques were developed to reduce the quantity of concrete needed. This is highly dependent upon geological considerations. In particular, the rock foundations must be able to support the forces imposed by the dam, and the seismic effects of potential earthquakes. Gravity dams work by holding water back by way of their own weight. A gravity dam can be described as a long series of heavy vertical, trapezoidal structural elements firmly anchored at the base. It is generally a straight wall of masonry that resists the applied water-pressure by its sheer weight. The strength of a gravity dam ultimately depends on its weight and the strength of its base.

An arch dam, on the other hand, relies on its shape to withstand the pressure of the water behind it. The arch curves back upstream, and the force exerted by the water is transferred through the dam into the river valley walls and to the river floor. They are normally constructed in deep gorges where the geological foundations are very sound. The Hoover Dam in the United States is an example of a concrete arch dam.

The buttress dam uses much less concrete than the gravity dam, and also relies on its shape to transfer the water load. Buttress dams were developed in areas where materials were scarce or expensive, but labor was available and cheap. They have been built primarily for purposes of irrigation. The dams are particularly suited for wide valleys. They have a thin facing supported at an incline by a series of buttresses. The buttresses themselves come in a variety of shapes, including the multiple arch and the simple slab deck (see Figure 3). The weight of the concrete is transferred to bedrock through the downstream legs or “buttresses” of the structure. The Coolidge Dam near Globe, Arizona is an example of a buttress dam, constructed of three huge domes of reinforced concrete.

Using water as a source of power actually dates back more than 2,000 years when the Greeks used water to turn wheels to grind wheat into flour. The first recorded use of water power was a clock, built around 250 B.C.E., and since that time, falling water has provided power to grind corn, wheat, and sugar cane, as well as to saw mills. In the tenth

century, water wheels were used extensively in the Middle East for milling and irrigation. One of these dams, built at Dizful (Iran), raised the water 190 feet and supplied the residents with water to grind corn and sugar cane.

The discoveries associated with electromagnetism in the early nineteenth century had a major impact on the development of hydropower. The development of electric power generators and the fact that electric power was the only form of energy in a “ready to use” state which can be transmitted over long distances have been particularly significant to hydroelectricity. Dams located away from population centers could be useful generators if there was a way to supply the consumers. Water turbines were also developed during the nineteenth century as a natural successor to the water wheel. The high performance and small size of the turbine relative to the water wheel were important advancements. Combining the technology of electric generators, turbines, and dams resulted in the development of hydroelectric power.

Water was first used to generate electricity in 1880 in Grand Rapids, Michigan when a water turbine was used to provide storefront lighting to the city. In 1882—only two years after Thomas Edison demonstrated the incandescent light bulb—the first hydroelectric station to use Edison’s system was installed on the Fox River at Appleton, Wisconsin. In 1881, construction began on the first hydroelectric generating station on the Niagara River in Niagara Falls on the New York-Canadian border. For twenty years, this project met the small electricity needs of the city. Water from the upper Niagara River fell 86 feet down a flume (a narrow gorge with a stream running through it) onto spinning water wheels on the lower river to generate electricity. The electricity was used to run the equipment of a paper company, other small factories, and sixteen open arc-lights on village streets. By 1896, the first long-distance transmission of electricity allowed the Niagara Falls project to provide electricity to Buffalo, New York—some 26 miles away.

By the early twentieth century, hydroelectric power was providing more than 40% of electricity generation in the United States. In 1940, hydropower supplied approximately three-fourths of all the electricity consumed in the West and Pacific Northwest, and still supplied approximately one-third of the total U.S. electricity supply. Although hydroelectricity’s share of total electricity generation has since fallen to approximately 10% in the United States, hydroelectricity provides almost one-fifth of the total electricity generation in the world.

Hydroelectric Energy

Hydroelectric energy, also called hydroelectric power or hydroelectricity, is a form of energy that harnesses the power of water in motion – such as water flowing over a waterfall – to generate electricity. People have used this force for millennia. Over two thousand years ago, people in Greece used flowing water to turn the wheel of their mill to ground wheat into flour.

Since hydroelectric energy is produced by the force of flowing or falling water. The capacity to produce this energy is dependent on both the available flow and the height from which it falls. Building up behind a high dam, water accumulates potential energy. This is transformed into mechanical energy when the water rushes down the sluice and strikes the rotary blades of turbine. The rotation of the turbine spins electromagnets which generate current in stationary coils of wire. Finally, the current is put through a transformer where the voltage is increased for long distance transmission over power lines.

Most hydroelectric power plants have a reservoir of water, a gate or valve to control how much water flows out of the reservoir, and an outlet or place where the water ends up after flowing downward. Water gains potential energy just before it spills over the top of a dam or flows down a hill. The potential energy is converted into kinetic energy as water flows downhill. The water can be used to turn the blades of a turbine to generate electricity, which is distributed to the users.

There are three different types of hydroelectric energy plants, the most common being an impoundment facility. In an impoundment facility, a dam is used to control the flow of water stored in a pool or reservoir. When more energy is needed, water is released from the dam. Once water is released, gravity takes over and the water flows downward through a turbine. As the blades of the turbine spin and power a generator.

Another type of hydroelectric energy plant is a diversion facility. This type of plant is unique because it does not use a dam. Instead, it uses a series of canals to channel flowing river water toward the generator-powering turbines.

The third type of plant is called a pumped-storage facility. This plant collects the energy produced from solar, wind, and nuclear power and stores it for future use. The plant stores energy by pumping water uphill from a pool at a lower elevation to a reservoir located at a higher elevation. When there is high demand for electricity, water located in the higher pool is released. As this water flows back down to the lower reservoir, it turns a turbine to generate more electricity.

In the process of electricity generation, the moving water pushes the turbine blades which turns the rotor, the moving part of the electric generator. When coils of wire on the rotor sweep past the stationary coil of the generator (the stator), electricity is produced. Thus, a hydraulic turbine converts the energy of flowing water into mechanical energy after which a hydroelectric generator converts this mechanical energy into electricity. The operation of a generator is based on the principles discovered by Faraday. He found that when a magnet is moved past a conductor, it causes electricity to flow. In a large generator, electromagnets are made by circulating direct current through loops of wire wound around stacks of magnetic steel laminations (field poles) which are mounted on the perimeter of the rotor. The rotor is attached to the turbine shaft, and rotates at a fixed speed. When the rotor turns, it causes the field poles (the electromagnets) to move past the conductors mounted in the stator. This, in turn, causes electricity to flow and a voltage to develop at the generator output terminals.

Hydroelectric energy is the most commonly-used renewable source of electricity. China is the largest producer of hydroelectricity. Other top producers of hydropower around the world include the United States, Brazil, Canada, India, and Russia. Approximately 71% of all of the renewable electricity generated on Earth is from hydropower.

Pumped storage is a method of keeping water in reserve for peak period power demands by pumping water that has already flowed through the turbines back up a storage pool above the power plant at a time when customer demand for energy is low, such as during the middle of the night. The water is then allowed to flow back through the turbine-generators at times when demand is high and a heavy load is placed on the system. The reservoir acts much like a battery, storing power in the form of water when demands are low and producing maximum power during daily and seasonal peak periods. An advantage of pumped storage is that hydroelectric generating units are able to start up quickly and make rapid adjustments in output. They operate efficiently when used for one hour or several hours. Because pumped storage reservoirs are relatively small, construction costs are generally low compared with conventional hydropower facilities.

As a form of renewable energy, hydropower does not pollute the water or the air. However, hydropower facilities can have large environmental impacts by changing the environment and affecting land use, homes, and natural habitats in the dam area. Most hydroelectric power plants have a dam and a reservoir. These structures may obstruct fish migration and affect their populations. Operating a hydroelectric power plant may also change the water temperature and the flow of the river. These changes may harm native plants and animals in the river and on land. Reservoirs may cover homes, important natural areas, agricultural land, and archaeological sites. So, building dams can require relocating people. Methane, a strong greenhouse gas, may also form in some reservoirs and be emitted to the atmosphere.

Considerable efforts have been made to reduce environmental problems associated with hydropower operations, such as providing safe fish passage and improved water quality as well as efforts to ensure the safety of dams. Yet, many unanswered questions remain related to the best method maintain the economic viability of hydropower in the face of increased demands to protect fish and other environmental resources.

There are many benefits for using hydro resources to produce electricity. First, hydropower is a renewable resource; oil, natural gas, and coal reserves may be depleted over time. Second, hydro resources are indigenous. A country that has developed its hydroelectric resources does not have to depend on other nations for its electricity; hydroelectricity secures a country's access to energy supplies. Third, hydroelectricity is environmentally friendly. It does not emit greenhouse gases, and hydroelectric dams can be used to control floods, divert water for irrigation purposes, and improve navigation on a river.

There are, however, disadvantages to developing hydroelectric power. Hydroelectric dams typically require a great deal of land resources. In conventional hydroelectric projects, a dam typically is built to create a reservoir that will hold the large amounts of water needed to produce power. Further, constructing a hydroelectric dam may harm the ecosystem and affect the population surrounding a hydro project. Environmentalists often are concerned related to the adverse impact of disrupting the flow of a river for fish populations and other animal and plant species. People often must be relocated so that a dam's reservoir may be created. Large-scale dams cause the greatest environmental changes and can be very controversial because of a requirement to relocate people so that a reservoir can be built to serve the dam.

Another potential problem for hydroelectricity is the possibility of electricity supply disruptions. A severe drought can mean that there will not be enough water to operate a hydroelectric facility. Communities with high dependence on the hydroelectric resources may find themselves struggling with electricity shortages in the form of brown-outs and black-outs.

This article begins with a description of how hydroelectricity works, from the beginning of the hydrological cycle to the point at which electricity is transmitted to homes and businesses. The history of the dam is outlined and how dams evolved from structures used for providing a fresh water supply to irrigation and finally to providing electricity. The history of hydropower is considered and the different hydroelectric systems (i.e., conventional, run-of-river, and pumped storage hydroelectricity) currently in use are discussed.

See also: Hydroelectric Energy.

Hydroelectric Power

Hydroelectric power is a widely used renewable source of energy. The idea behind hydroelectric power is conceptually simple. At a geographically and technologically appropriate location along the path of a river, a dam is built creating a huge reservoir lake on the high side of the dam. As reservoir water pours over the dam because of gravity, it turns a turbine which then drives an electric generator, producing electricity.

Hydroelectric power has many attractive advantages such as (i) there are no carbon dioxide emissions or emissions of other serious pollutants during the production of electricity, (ii) large amounts of power are generated in a hydroelectric plant, comparable to that in a coal or nuclear plant, (iii) the conversion efficiency of fluid kinetic energy to electricity is high since no thermal steam cycle is involved, (iv) except in rare cases of extended drought, the power is available continuously for base load electricity, (v) the cost of electricity is low, typically comparable to that of coal plants, and (vi) the fuel reserves are effectively infinite.

Hydroelectric power is clearly a renewable energy source, but there are two disadvantages to hydroelectric power: (i) most of the suitable rivers already have dams and, therefore, expansion of hydroelectric power is difficult since there are few, if any, unutilized technologically attractive sites available, and (ii) although not a major problem for early dams, environmental issues will have a much larger impact on any future hydroelectric plants. The main issue is the large amount of land that is flooded to form the reservoir lake. Often this, land could be used for agricultural or recreational purposes, so there is a tradeoff that must be evaluated before changing its use to electricity production.

As one part of the production of hydroelectric power, dams are placed on a river or other medium-sized body of water to create a reservoir. This reservoir releases water through a turbine, which is spun by the water and powers a generator. Dams and similar constructs also have a variant known as a pumped storage plant, which uses pumps (consuming energy) to move water from a lower reservoir/water source to a higher one, which can then flow back through the turbines to reproduce the energy. As the name suggests, this method is a way for hydroelectric power sources to store energy until it is needed. Dams have been shown to be particularly harmful to their surrounding ecosystem, however, causing shifts in sediment depositories, flooding surrounding land, and killing some of the wildlife that travels through them.

Hydroelectric Power Generation

Hydroelectricity depends on the availability of water, which is provided in the form of rain or melting snow, which fills the reservoirs that fuel the hydroelectric plant. Most of this water comes from oceans, but rivers and lakes and other, smaller bodies of water also contribute. The heat of the sun causes the water from these sources to evaporate (that is, to change the water from its liquid state into a gaseous one). The water remains in the air as an invisible vapor until it condenses and changes first into clouds and eventually into rain. Condensation is the opposite of evaporation. It occurs when the water vapor changes from its gaseous state back into its liquid state.

Condensation occurs when air temperatures cool. The cooling occurs in one of two ways. Either the air vapor cools as it rises and expands or as it comes into contact with a cool object such as a cold landmass or an ice-covered area.

Air rises for several reasons. It can be forced up as it encounters a cooler, denser body of air, or when it meets mountains or other raised land masses. It can rise as it meets a very warm surface, like a desert, and become more buoyant than the surrounding air. Air also can be forced to rise by storms—during tornadoes, particles of air circling to the center of a cyclone collide and are forced up. When the water vapor collides with a cold object, it can become fog, dew, or frost as it condenses. The vapor cools as it rises into the atmosphere and condenses to form clouds and, sometimes, rain.

In order for rain to form, there must be particles in the air (i.e., dust or salt) around which the raindrop can form and which are at temperatures above freezing. When the particles are cooled to temperatures below the freezing point, water condenses around them in layers. The particles grow heavy enough that they eventually fall through the clouds in the form of raindrops or—if the air temperature is below the freezing point, all the way to the ground — as snow, sleet, or hail.

Much of the rain that reaches the ground runs off the surface of the land and flows into streams, rivers, ponds, and lakes. Small streams lead to bigger ones, then to rivers, and eventually back to the oceans where the evaporation process begins all over again. Although water continuously changes from solid to liquid to gas, the amount of water on the earth remains the same, and currently, there is as much water as there was hundreds of millions of years ago.

This water cycle – the process of moving water from oceans to streams and back again – is essential to the generation of hydroelectricity. Moving water can be used to perform work and, in particular, hydroelectric power plants employ water to produce electricity. The combination of abundant rainfall and the right geographical conditions is essential for hydroelectric generation.

Hydroelectric power is generated by flowing water driving a turbine connected to an electric generator. The two basic types of hydroelectric systems are those based on falling water and those based on natural river current, both of which rely on gravitational energy. Gravitational forces pull the water down either from a height or through the natural current of a river. The gravitational energy is converted to kinetic energy. Some of this kinetic energy is converted to mechanical (or rotational) energy by propelling turbine blades that activate a generator and create electricity as they spin.

The amount of energy created by a hydroelectric project depends largely upon two factors: the pressure of the water acting on the turbine and the volume of water available. Water that falls 1,000 feet generates approximately twice as much electric power as the same volume of water falling only 500 feet. In addition, if the amount of water available doubles, so does the amount of energy.

The falling water hydrosystem is comprised of a dam, a reservoir, and a power generating unit. The dam is constructed so that a reservoir is created within which water accumulates and may be stored until it is needed. Water is released as required to meet electricity demands of customers. At the bottom of the dam wall is the water intake. The water intake controls when and how much water is moved into a steel container (the penstock). Gravity causes the water to fall through the penstock. This pipe delivers the running water to a turbine – a propeller-like machine with blades like a large fan. The water pushes against the turbine blades, and the blades turn. Because the turbine is connected to an electric generator, as the turbine gains speed, it powers the generator and electricity is produced. The largest falling water facility in the United States is the Grand Coulee hydroelectric project on the Columbia River, in Washington State. Indeed, the largest power production facilities in North America are found at the Grand Coulee Dam project where an average 21 billion kilowatt-hours of electricity are produced each year.

The second type of hydroelectric plant is called a run-of-the-river system. In this case, the force of the river current applies pressure to the turbine blades to produce electricity. Run-of-the-river systems do not usually have reservoirs and cannot store substantial quantities of water. As a result, power production from this type of system depends on the river flow—the electricity supply is highly dependent upon seasonal fluctuations in output. Run-of-river projects are most successful when there are large flows in flat rivers or when a high natural geological drop is present, and when the required electricity output is below the maximum potential of the site.

Hydropower systems, as in all electricity-producing systems, require a generator to create the electricity. An electric generator is a device that converts mechanical energy into electric energy. The process is based on the relationship between magnetism and electricity. When a wire or any other electrically conductive material moves across a magnetic field, an electric current occurs in the wire. In a power plant, a strong electromagnet, called a rotor, is attached to the end of a shaft. The shaft is used to spin the rotor inside a cylindrical iron shell with slots—called a stator. Conducting wires are wound through the slots of the stator. When the rotor spins at a high rate of speed, an electric current flows through the conducting wires.

In a hydroelectric system, flowing water is used to propel a turbine that spins the shaft connected to the generator and creates the electric current. The kinetic energy of the moving water is changed into rotational energy and thereby

causes the turbine blades to rotate. The turbine is attached to an electric generator, and the rotational energy of the turbine is then converted to electric energy. The electricity then leaves the generator and is carried to the transformers where the electricity can travel through electric power lines and is supplied to residential, commercial, and industrial consumers. After the water has fallen through the turbine, it continues to flow downriver and to the ocean where the water cycle begins all over again.

Pumped storage is an extended version of the falling water hydroelectric system. In a pumped storage system, two water sources are required—a reservoir located at the top of the dam structure and another water source at the bottom. Water released at one level is turned into kinetic energy by its discharge through high-pressure shafts that direct the downflow through the turbines connected to the generator. The water flows through the hydroelectric generating system and is collected in a lower reservoir. The water is pumped back to the upper reservoir once the initial generation process is complete. Generally, this is done using reversible turbines—that is, turbines that can operate when the direction of spinning is reversed. The pump motors are powered by conventional electricity from the national grid. The pumping process usually occurs overnight when electricity demand is at its lowest. Although the pumped storage sites are not net energy producers—pumped storage sites use more energy pumping the water up to the higher reservoir than is recovered when it is released—they are still a valuable addition to electricity supply systems. They offer a valuable reserve of electricity when consumer demand rises unexpectedly or under exceptional weather conditions. Pumped storage systems are normally used as “peaking” units.

Hydroelectric Power – Turbines

Hydropower plants capture the energy of falling water to generate electricity. A turbine converts the kinetic energy of falling water into mechanical energy. Then, a generator converts the mechanical energy from the turbine into electrical energy.

While there are only two types of turbines – the impulse turbine and the reaction turbine – there are many variations. The specific type of turbine to be used in a powerplant is not selected until all operational studies and cost estimates are complete, and the selection of the turbine depends largely on the site conditions.

An impulse turbine is a horizontal or vertical wheel that uses the kinetic energy of water striking its buckets or blades to cause rotation. The wheel is covered by a housing, and the buckets or blades are shaped so they turn the flow of water approximately 170 degrees inside the housing. After turning the blades or buckets, the water falls to the bottom of the wheel housing and flows out.

A reaction turbine is a horizontal or vertical wheel that operates with the wheel completely submerged, a feature which reduces turbulence. In the reaction turbine, water at a central point is under pressure and escapes from the ends of the blades, causing rotation.

Hydrogasification

Another option for conversion of biomass to useable products is the hydrogasification concept which, although not yet attempted on a commercial scale with biomass, has been used with coal.

Direct addition of hydrogen to coal under high pressure forms methane. This reaction is called hydrogasification that may be written as:

Or

This reaction is exothermic and is thermodynamically favored at low temperatures ($T < 670^{\circ}\text{C}$, $< 1,240^{\circ}\text{F}$), unlike both steam and carbon dioxide gasification reactions. However, at low temperatures, the reaction rate is inevitably too slow. Therefore, high temperature is always required for kinetic reasons, which in turn requires high pressure that is also preferred from equilibrium considerations. This reaction can be catalyzed by potassium carbonate (K_2CO_3), nickel, iron chlorides, and iron sulfate. However, use of catalyst in coal gasification renders somewhat serious economic constraints due to the low raw material value as well as difficulty in recovering and reusing the catalyst. Therefore, catalytic coal gasification has not been practiced much.

See also: Gasification, Gasification of Biomass.

Hydrogen

Hydrogen, as atomic hydrogen, is the most abundant chemical element in the universe, making up 75% w/w normal matter and more than 90% by number of atoms.

Hydrogen (H_2) is a promising energy carrier of the future: It can be derived from a variety of energy sources and used in fuel cells with high efficiency. Hydrogen is a completely clean burning fuel – the product is water (H_2O), and there are no oxides of sulfur or carbon that can cause environmental pollution. The major issue with this form of alternative energy is that it is mostly derived from the use of natural gas and fossil fuels. As such, it could be argued that the emissions created to extract it counteract the benefits of its use. The process of electrolysis, which is essential for the splitting of water into hydrogen and oxygen, makes this less of an issue. However, electrolysis still ranks below the previously mentioned methods for obtaining hydrogen, though research continues to make it more efficient and cost-effective.

Like electricity, hydrogen is an energy carrier (not an energy source), meaning it can store and deliver energy in an easily usable form. Although abundant on earth as an element, hydrogen combines readily with other elements and is almost always found as part of some other substance, such as water (H_2O), or hydrocarbons like natural gas (which consists primarily of methane, CH_4). Hydrogen is also found in biomass, which includes all plants and animals.

Despite its simplicity and abundance, hydrogen does not occur naturally as a gas on the Earth – it is always combined with other elements in the form of naturally-occurring materials. Hydrogen is also found in many organic compounds, notably natural gas, crude oil, heavy crude oil, extra heavy crude oil, and tar sand bitumen which are sources for the currently-used liquid fuels.

The most common industrial methods for producing hydrogen include steam reformation of natural gas, coal gasification, and splitting water with electricity typically generated from fossil fuels. Hydrogen can be separated from hydrocarbon derivatives through the application of heat – a process known as *reforming*. Currently, most hydrogen is made this way from natural gas (steam-methane reforming). An electrical current can also be used to separate water into its components of oxygen and hydrogen (electrolysis), and various species of algae and bacteria, using sunlight as their energy source, even give off hydrogen under certain conditions. Typically, the hydrogen-producing processes are energy-intensive industrial processes that release carbon dioxide and other greenhouse gases and pollutants as by-products. Some microorganisms produce hydrogen naturally, and biotechnologies based on these microbial systems could lead to the development of clean, renewable sources of hydrogen.

The environmental and health benefits are also seen at the source of hydrogen production if derived from low- or zero-emission sources, such as solar, wind, and nuclear energy and fossil fuels with advanced emission controls and carbon sequestration. Because the transportation sector accounts for approximately one-third of carbon dioxide emissions, using these sources to produce hydrogen for transportation can cut greenhouse gas emissions.

The energy content of hydrogen (by volume) is low which makes storing hydrogen a challenge because it requires high pressures, low temperatures, or chemical processes to be stored compactly. Overcoming this challenge is important for light-duty vehicles because they often have limited size and weight capacity for fuel storage.

Typically, the storage capacity for hydrogen in light-duty vehicles should enable a driving range of more than 300 miles to meet consumer needs. Because hydrogen has a lower volumetric energy density than that of gasoline, storing this much hydrogen on a vehicle currently requires a larger tank at higher pressure than other gaseous fuels.

The hydrogen-energy based economy is a proposed system of delivering energy using hydrogen. The advocates promote hydrogen as a potential fuel for motive power (including cars and boats), the energy needs of buildings, and

portable electronics. Free hydrogen does not occur naturally in quantity, but can be generated by steam reforming of hydrocarbon derivatives, electrolysis of water, and a variety of other methods.

In the future, hydrogen could also join electricity as an important energy carrier. An energy carrier moves and delivers energy in a usable form to consumers. Renewable energy sources, such as the sun and wind, cannot produce energy all the time. But they could, for example, produce electric energy and hydrogen, which can be stored until it is needed. Hydrogen can also be transported (like electricity) to locations where it is needed.

Public awareness of clean burning and energy-efficient hydrogen has propelled unprecedented interest in hydrogen technology and fuel cell research and development. Many experts in the world predict the future as *hydrogen economy*. For the hydrogen economy to be fully arriving, a long list of technological advances must be accomplished, which include technologies for inexpensive generation, safe distribution and storage, safe and efficient materials for hydrogen handling, hydrogen internal combustion engine, hydrogen fuel cells, and loss prevention.

Hydrogen Economy

Hydrogen is the most abundant element in the universe. It can combine with oxygen to form water, H_2O . This process releases energy, so hydrogen can be used as a fuel. However, natural free hydrogen (hydrogen not already bound up in water or some other molecule) is rare on Earth, so if large quantities are desired, they must be manufactured. This can be done either by reforming methane (CH_4), or by using electricity or catalysts to split water (H_2O) into molecular hydrogen (H_2) and molecular oxygen (O_2), respectively. Hydrogen can be combined with oxygen in a fuel cell, which produces electricity, or in a flame or explosion, which produces heat. In either case, the only chemical byproduct of the reaction is water.

Free hydrogen is found only in trace amounts in nature, so cannot be extracted as a primary chemical fuel. It is therefore considered not an energy source but an energy carrier, a way of moving energy from a primary source to an end-user, much like electricity. Approximately 40 million tons of hydrogen are manufactured each year from natural gas (methane) using a method called the Haber process. This process—named after its discoverer, German chemist Fritz Haber (1868-1934)—exploits the fact that at high temperatures, methane (CH_4 , where C stands for carbon) combines with water in the form of steam to release hydrogen and carbon monoxide (CO). In chemical notation, the reaction is written as follows:

Energy is lost in this reaction—that is, less energy is obtained by burning the hydrogen than could have been obtained by burning the methane from which it was made. Specifically, 15% of the energy in the methane is lost steam reformation. This energy cost may be worthwhile when there is a task that hydrogen can be used for that methane cannot, or if some other value is obtained. For example, more useful energy can be extracted from a given amount of hydrogen in a fuel cell than by burning it explosively with oxygen, as is done in the cylinders of a standard engine. In fact, by reforming methane into hydrogen and then combining the hydrogen with oxygen in a fuel cell, more energy can be extracted from the original methane than by burning it directly, despite the energy lost in the conversion.

Hydrogen is ultimately no cleaner than the energy sources used to produce it. Carbon monoxide is created during the extraction of hydrogen from methane, which, if released into the atmosphere eventually becomes carbon dioxide. However, it is possible to capture this carbon in the large facilities where hydrogen is produced and inject it deep underground to prevent it from causing climate change. Alternatively, there are industrial processes that capture the carbon as a black powder that can be sold as a useful product (carbon black) or sequestered from the atmosphere with relative ease.

Natural gas (which is mostly methane, and is the source of the methane used to manufacture hydrogen) has the advantage of being fairly cheap. There is a well-established supply system for it. However, natural gas has the disadvantage that it is a fossil fuel and will someday be all used up. It is also, like petroleum, often obtained from politically unstable parts of the world. It must be chilled to low temperatures (-160°C , -260°F) and is transported around the

world in gigantic tankers, each one carrying up to 30 million gallons (114 million liters) of super-cold liquid gas that contains as much energy as a small nuclear weapon.

A more attractive way to produce hydrogen than steam reformation of methane, in many ways, is the production of hydrogen by electrolysis using electricity derived from truly inexhaustible resources such as wind power and solar cells. An economy based on electricity from the wind and sunlight, which would use hydrogen wherever a portable liquid fuel was needed, could in theory continue for many millions of years—as long as the sun continues to shine. Such a system might even be affordable.

Despite the many desirable aspects of a global hydrogen economy, transition to a hydrogen economy may be difficult for a number of reasons. Almost every aspect of the possible hydrogen economy is fiercely debated among experts. Some of the issues raised by critics of the concept, along with some of the counterpoints mentioned by its defenders, are as follows: (i) hydrogen is dangerous, and (ii) hydrogen is difficult to handle.

In the first issue (i.e., hydrogen is dangerous), the accident relating to the burning of the airship Hindenburg on May 6, 1937, in Manchester Township, New Jersey is often cited in this respect. Images of the burning hydrogen-filled Hindenburg are often recalled as proof of the dangers of hydrogen. Conversely, gasoline and the other liquid fuels, on which are relied upon for most transportation, are also dangerous and explosive, both as liquids and vapors. In relation to the second issue (i.e., hydrogen is difficult to handle), the hydrogen atom is the smallest and lightest of all atoms, and the hydrogen molecule is the smallest and lightest of all molecules. A given volume of hydrogen contains only 30% as much energy as the same volume of natural gas at the same temperature and pressure; at 2,500 psi, a given volume of hydrogen contains only 6% as much energy as an equal volume of gasoline leading to the concept that hydrogen is therefore bulky and must be transported under pressure, making it difficult to fit enough hydrogen compactly into a vehicle to give it the range of a gasoline-burning conventional or hybrid car.

In the modern world, these aspects of hydrogen behavior require caution but sufficient control are in place to minimize these potential dangers.

Hydrogen – Environmental Impact

Much of the impact of adopting hydrogen as an energy source would be positive for the environment. The use of hydrogen would likely come with a reduction of the use of fossil fuels as energy sources. With this reduction would perhaps come a reduction in global warming because fossil fuel use is believed to be an important contributor to global warming.

However, the production of hydrogen can potentially affect the environment in a negative way. Depending on the production method, carbon dioxide and other negative emissions can enter the atmosphere while hydrogen is being made. This issue can be addressed by catching and storing the carbon dioxide, but even this storage can potentially affect the environment. However, if environmentally friendly, renewable resources such as solar or wind are used to power the means of producing hydrogen, the negative impact can be eliminated.

Another issue is that if hydrogen becomes widely used, it could leak into the atmosphere. If the amount is significant enough, this hydrogen could change the percentage of hydrogen present in Earth's atmosphere. Some scientists believe that this could have a profound effect on the atmosphere, including increasing the size of the hole in the ozone layer. More hydrogen in the atmosphere could also lead to more high altitude clouds and increase the number of soil microbes that rely on hydrogen as their primary nutrient. The soil microbe increase could change the ecology of the Earth. However, there are soil micro-organisms that consume hydrogen as well, and they might be able to balance these problems out. The outcome of putting more hydrogen in the atmosphere is uncertain.

A final environmental question is what to do with the water or water vapor that would be produced by cars using hydrogen fuel cells. Since such water is pure, it will freeze in temperatures below 0°C (32°F).

Hydrogen Fuel

Hydrogen fuel is a zero-emission fuel, which uses electrochemical cells, or combustion in internal engines to power vehicles and electric devices. It is also used in the propulsion of spacecraft and can potentially be mass-produced and

commercialized for passenger vehicles and aircraft. It is a completely clean burning fuel in that its only by-product is water.

As the first element on the Periodic Table of the elements, hydrogen is the lightest element on earth. Since hydrogen gas is so light, it rises in the atmosphere and is therefore rarely found in its pure form (H_2). In a flame of pure hydrogen gas, burning in air, the hydrogen (H_2) reacts with oxygen (O_2) to form water (H_2O) and releases heat. Other than water, hydrogen combustion may yield small amounts of nitrogen oxides.

Pure hydrogen does not occur naturally, and the process takes a substantial amount of energy to manufacture hydrogen. There are different ways to manufacture it, such as, electrolysis and steam-methane reforming process. Once manufactured, this energy carrier can be delivered to fuel cells and generate electricity and heat, or burned to run a combustion engine. Hydrogen fuel can provide motive power for cars, boats, and airplanes, portable fuel cell applications, or stationary fuel cell applications, which can power an electric motor. In each case, hydrogen is combined with oxygen to form water.

Because the process requires a high-energy input, commercial hydrogen is very inefficient. Use of a biological vector as a means to split water, and therefore produce hydrogen gas, would allow for the only energy input to be solar radiation. Biological vectors can include bacteria or more commonly algae. This process is known as biological hydrogen production. It requires the use of single-celled organisms to create hydrogen gas through fermentation. Without the presence of oxygen, also known as an anaerobic environment, regular cellular respiration cannot take place and a process known as fermentation takes over.

Hydrogen – Production

Hydrogen can be produced from diverse domestic resources with the potential for near-zero greenhouse gas emissions. Once produced, hydrogen generates electrical power in a fuel cell, emitting only water vapor and warm air. It holds promise for growth in both the stationary and transportation energy sectors.

Hydrogen can be produced from resources like natural gas, coal, solar energy, wind, and biomass. When used to power highly efficient fuel cell electric vehicles, hydrogen holds the promise of helping conserve petroleum and diversifying the options for energy transportation.

Natural gas is the most common feedstock for hydrogen production since it meets all the requirements for reformer feedstock. Natural gas typically contains more than 90% methane and ethane with only a few percent of propane and higher boiling hydrocarbon derivatives. Natural gas contains traces of carbon dioxide with some nitrogen and other impurities. Purification of natural gas, before reforming, is usually relatively straightforward. Traces of sulfur must be removed to avoid poisoning the reformer catalyst; zinc oxide treatment in combination with hydrogenation is usually adequate.

Low-boiling refinery gas, containing a substantial amount of hydrogen, can be an attractive steam reformer feedstock since it is produced as a by-product. Processing of refinery gas will depend on its composition, particularly the levels of olefins and of propane and heavier hydrocarbon derivatives. Olefin derivatives, that can cause problems by forming coke in the reformer, are converted to saturated compounds in the hydrogenation unit. Higher boiling hydrocarbon derivatives in refinery gas can also form coke, either on the primary reformer catalyst or in the pre-heater. If there is more than a few percent of C_3 and higher compounds, a promoted reformer catalyst should be considered, in order to avoid carbon deposits.

Refinery gas from different sources varies in suitability as hydrogen plant feed. Catalytic reformer off-gas for example, is saturated, low in sulfur, and often has high hydrogen content. The process gases from a coking unit or from a fluid catalytic cracking unit are much less desirable because of the content of unsaturated constituents. In addition to olefins, these gases contain substantial amounts of sulfur that must be removed before the gas is used as

feedstock. These gases are also generally unsuitable for direct hydrogen recovery since the hydrogen content is usually too low. Hydrotreater off-gas lies in the middle of the range. It is saturated, so it is readily used as hydrogen plant feed. Content of hydrogen and higher-boiling hydrocarbon derivatives depends to a large extent on the upstream pressure. Sulfur removal will generally be required.

Under certain conditions, green algae and cyanobacteria can use water-splitting photosynthetic processes to generate molecular hydrogen (H_2) rather than fix carbon, the normal function of oxygenic photosynthesis.

Bidirectional hydrogenases in these organisms use electrons from the photosynthetic electron-transport chain to reduce protons to yield H_2 . Biophotolysis holds potential for the scale of hydrogen production necessary to meet future energy demand. This approach to hydrogen production is promising because the source of electrons or reducing power required to generate hydrogen is water – a clean, renewable, carbon-free substrate available in virtually inexhaustible quantities.

Another advantage of biophotolysis is the more efficient conversion of solar energy to hydrogen. Reengineering microbial systems for the direct production of hydrogen from water eliminates inefficiencies associated with carbon fixation and biomass formation. Theoretically, the maximal energetic efficiency for direct biophotolysis is approximately 40% compared with a maximum of approximately 1% for hydrogen production from biomass.

Each process for the production of hydrogen-producing method has advantages and disadvantages. Electrolysis is considered to be the most environmentally-benign procedure because it produces no by-products that are harmful to the environment. In addition, it has a potentially positive by-product: oxygen which can be captured and used elsewhere. Although the large-scale production of hydrogen by electrolysis is generally an expensive process when electricity is used to create the electric currents, the use of renewable energy sources such as hydroelectric power, hydropower, solar energy or even nuclear power are used to produce the current can lower the cost of the production process. Another source of energy could be obtained through the use of biomass: waste, sewage, and agricultural residue are all endlessly renewable and have little negative effect on the environment.

Hydrogen – Production By Pyrolysis

Natural gas is readily available and offers a relatively rich stream of methane with lower amounts of ethane, propane, and butane also present. The thermocatalytic decomposition of natural gas hydrocarbon derivatives offers an alternate method for the production of hydrogen:

If a hydrocarbon fuel such as natural gas (methane) is to be used for hydrogen production by direct decomposition, then the process that is optimized to yield hydrogen production may not be suitable for production of high-quality carbon black by-product intended for the industrial rubber market. Moreover, it appears that the carbon produced from high-temperature (850-950°C; 1,560-1,740°F) direct thermal decomposition of methane is a soot-like material with high tendency for the catalyst deactivation. Thus, if the object of methane decomposition is hydrogen production, the carbon by-product may not be marketable as high-quality carbon black for rubber and tire applications.

The production of hydrogen by direct decomposition of hydrogen sulfide is also a possibility. The process is highly endothermic, and equilibrium yields are poor. At temperatures less than 1,500°C (2,730°F), the thermodynamic equilibrium is unfavorable toward hydrogen formation. However, in the presence of catalysts such as platinum-cobalt (at 1,000°C; 1,830°F), disulfides of molybdenum or tungsten Mo or W at 800°C (1,470°F), or other transition metal sulfides supported on alumina (at 500 to 800°C; 930 to 1,470°F), decomposition of hydrogen sulfide proceeds rapidly. In the temperature range of approximately 800 to 1,500°C (1,470 to 2,730°F), thermolysis of hydrogen sulfide can be treated simply:

where $x = 2$. Outside this temperature range, multiple equilibria may be present depending on temperature, pressure, and relative abundance of hydrogen and sulfur.

Above approximately 1,000°C (1,830°F), there is a limited advantage to using catalysts since the thermal reaction proceeds to equilibrium very rapidly. The hydrogen yield can be doubled by preferential removal of either H_2 or sulfur from the reaction environment, thereby shifting the equilibrium. The reaction products must be quenched quickly after leaving the reactor to prevent reversible reactions.

Hydrogen Production Chemistry

In the steam reforming process, low-boiling hydrocarbon derivatives such as methane are reacted with steam to form hydrogen:

H is the heat of reaction. A more general form of the equation that shows the chemical balance for higher-boiling hydrocarbon derivatives is:

The reaction is typically carried out at approximately 815°C (1,500°F) over a nickel catalyst packed into the tubes of a reforming furnace. The high temperature also causes the hydrocarbon feedstock to undergo a series of cracking reactions, plus the reaction of carbon with steam:

Carbon is produced on the catalyst at the same time that hydrocarbon is reformed to hydrogen and carbon monoxide. With natural gas or similar feedstock, reforming predominates and the carbon can be removed by reaction with steam as fast as it is formed. When higher-boiling feedstocks are used, the carbon is not removed fast enough and builds up thereby requiring catalyst regeneration or replacement. Carbon buildup on the catalyst (when high-boiling feedstocks are employed) can be avoided by addition of alkali compounds, such as potash, to the catalyst thereby encouraging or promoting the carbon-steam reaction.

However, even with an alkali-promoted catalyst, feedstock cracking limits the process to hydrocarbon derivatives with a boiling point less than of 180°C (350°F). Natural gas, propane, butane, and low-boiling naphtha are most suitable. Pre-reforming, a process that uses an adiabatic catalyst bed operating at a lower temperature, can be used as a pretreatment to allow heavier feedstocks to be used with lower potential for carbon deposition (coke formation) on the catalyst.

After reforming, the carbon monoxide in the gas is reacted with steam to form additional hydrogen (the water-gas shift reaction):

This leaves a mixture consisting primarily of hydrogen and carbon monoxide that is removed by conversion to methane:

The critical variables for steam reforming processes are (i) temperature, (ii) pressure, and (iii) the steam/hydrocarbon ratio. Steam reforming is an equilibrium reaction, and conversion of the hydrocarbon feedstock is favored by high temperature, which in turn requires higher fuel use. Because of the volume increase in the reaction, conversion is also favored by low pressure, which conflicts with the need to supply the hydrogen at high pressure. In practice, materials of construction limit temperature and pressure.

On the other hand, and in contrast to reforming, shift conversion is favored by low temperature. The gas from the reformer is reacted over iron oxide catalyst at 315 to 370°C (600 to 700°F) with the lower limit being dictated activity of the catalyst at low temperature.

Hydrogen can also be produced by partial oxidation (POX) of hydrocarbon derivatives in which the hydrocarbon is oxidized in a limited or controlled supply of oxygen:

The shift reaction also occurs, and a mixture of carbon monoxide and carbon dioxide is produced in addition to hydrogen. The catalyst tube materials do not limit the reaction temperatures in partial oxidation processes, and higher temperatures may be used that enhance the conversion of methane to hydrogen. Indeed, much of the design and operation of hydrogen plants involves protecting the reforming catalyst and the catalyst tubes because of the extreme temperatures and the sensitivity of the catalyst. In fact, minor variations in feedstock composition or operating conditions can have significant effects on the life of the catalyst or the reformer itself. This is particularly true of changes in molecular weight of the feed gas, or poor distribution of heat to the catalyst tubes.

Since the high temperature takes the place of a catalyst, partial oxidation is not limited to the lower-boiling feedstocks that are required for steam reforming. Partial oxidation processes were first considered for hydrogen production because of expected shortages of lower-boiling feedstocks and the need to have available a disposal method for higher-boiling, high-sulfur streams such as asphalt or petroleum coke.

Catalytic partial oxidation, also known as auto-thermal reforming, reacts oxygen with a low-boiling feedstock and by passing the resulting hot mixture over a reforming catalyst. The use of a catalyst allows the use of lower temperatures than in non-catalytic partial oxidation and which causes a reduction in oxygen demand.

The feedstock requirements for catalytic partial oxidation processes are similar to the feedstock requirements for steam reforming, and low-boiling hydrocarbon derivatives from refinery gas to naphtha are preferred. The oxygen substitutes for much of the steam in preventing coking and a lower steam/carbon ratio is required. In addition, because a large excess of steam is not required, catalytic partial oxidation produces more carbon monoxide and less hydrogen than steam reforming. Thus, the process is more suited to situations where carbon monoxide is the more desirable product such as, for example, as synthesis gas for chemical feedstocks.

Hydrogen Production Processes

In spite of the use of low-quality hydrogen (that contain up to 40% by volume hydrocarbon gases), a high-purity hydrogen stream (95%-99% by volume hydrogen) is required for hydrodesulfurization, hydrogenation, hydrocracking, and petrochemical processes. Hydrogen, produced as a by-product of refinery processes (principally hydrogen recovery from catalytic reformer product gases), often is not enough to meet the total refinery requirements, necessitating the manufacturing of additional hydrogen or obtaining supply from external sources.

Catalytic reforming remains an important process used to convert low-octane naphtha into high-octane gasoline blending components called reformate. Reforming represents the total effect of numerous reactions such as cracking, polymerization, dehydrogenation, and isomerization taking place simultaneously. Hydrogen, a significant by-product, is separated from reformate for recycling and use in other processes.

A catalytic reformer comprises a reactor section and a product-recovery section. More or less standard is a feed preparation section in which, by combination of hydrotreatment and distillation, the feedstock is prepared to specification. Most processes use platinum as the active catalyst. Sometimes, platinum is combined with a second catalyst (bimetallic catalyst) such as rhenium or another noble metal. There are many different commercial catalytic reforming processes including Platforming, Powerforming, Ultraforming, and Thermoform catalytic reforming. In the platforming process,

the first step is preparation of the naphtha feed to remove impurities from the naphtha and reduce catalyst degradation. The naphtha feedstock is then mixed with hydrogen, vaporized, and passed through a series of alternating furnace and fixed-bed reactors containing a platinum catalyst. The effluent from the last reactor is cooled and sent to a separator to permit removal of the hydrogen-rich gas stream from the top of the separator for recycling. The liquid product from the bottom of the separator is sent to a fractionator called a stabilizer (butanizer), and the bottom product (reformate) is sent to storage, and low-boiling gases butane derivatives pass overhead and are sent to the saturated gas plant.

Some catalytic reformers operate at low pressure (50-200 psi), and others operate at high pressures (up to 1,000 psi). Some catalytic reforming systems continuously regenerate the catalyst in other systems. One reactor at a time is taken off-stream for catalyst regeneration, and some facilities regenerate all of the reactors during turnarounds. Operating procedures should be developed to ensure control of hot spots during start-up. Safe catalyst handling is important, and care must be taken not to break or crush the catalyst when loading the beds, as the small fines will plug up the reformer screens. Precautions against dust when regenerating or replacing catalyst should also be considered, and a water wash should be considered where stabilizer fouling has occurred due to the formation of ammonium chloride and iron salts. Ammonium chloride may form in pretreater exchangers and cause corrosion and fouling. Hydrogen chloride from the hydrogenation of chlorine compounds may form acid or ammonium chloride salt.

Electrolytic processes use electricity to split water into hydrogen and oxygen in a unit called an electrolyzer. Like fuel cells, electrolyzers consist of an anode and a cathode separated by an electrolyte. The electrolyte determines the type of electrolyzer and its operating conditions.

In a polymer electrolyte membrane (PEM) electrolyzer, (i) water at the anode reacts to form oxygen and positively charged hydrogen ions (protons) and electrons that flow through the external circuit, (ii) the hydrogen ions move across the polymer electrolyte membrane to the cathode, and (iii) at the cathode, hydrogen ions combine with electrons from the external circuit to form hydrogen gas.

Alkaline electrolyzers are similar to polymer electrolyte membrane electrolyzers, but instead use an alkaline solution (of sodium or potassium hydroxide) as the electrolyte. Both PEM and alkaline electrolyzers operate at relatively low temperatures on the order of 80 to 100°C (176 to 212°F) and 100 to 250°C (212 to 480°F), respectively. A solid oxide electrolyzer, which has a solid ceramic electrolyte, generates hydrogen in a slightly different way and must operate at a higher temperature (500 to 800°C, 930 to 1,470°F) for the membranes to function properly. Solid oxide electrolyzers can effectively use heat available at these elevated temperatures (from various sources, including nuclear energy) to decrease the amount of electrical energy needed to produce hydrogen from water. In a solid oxide electrolyzer, (i) water at the cathode combines with electrons from the external circuit to form hydrogen gas and negatively charged oxygen ions, and (iii) the oxygen ions pass through the membrane and react at the anode to form oxygen gas and give up the electrons to the external circuit.

Polymer electrolyte membranes and alkaline electrolyzers can be smaller, appliance-sized equipment, and well suited for distributed hydrogen production. The source of the required electricity (including its cost and efficiency, as well as emissions resulting from electricity generation) must be considered when evaluating the benefits of hydrogen production via electrolysis.

Hydrogen Properties

Combustion

Combustion of hydrogen with the oxygen in the air. When the bottom cap is removed, allowing air to enter at the bottom, the hydrogen in the container rises out of top and burns as it mixes with the air. Hydrogen gas is highly flammable:

Gas gas liquid

Hydrogen gas forms explosive mixtures with air in concentrations from 4 to 74% v/v and with chlorine at 5 to 95% v/v. The explosive reactions may be triggered by spark, heat, or sunlight. The hydrogen autoignition temperature (the temperature of spontaneous ignition in air, is 500°C (932°F).

Isotopes

Hydrogen has three naturally occurring isotopes, denoted ^1H , ^2H , and ^3H . Other, highly unstable nuclei (^4H to ^7H) have been synthesized in the laboratory but not observed in nature.

The ^1H isotope is the most common hydrogen isotope, with an abundance of more than 99.98%. Because the nuclear of this isotope consists of only a single proton, it is given the descriptive but rarely used formal name *protium*.

The ^2H isotope, the other stable hydrogen isotope, is known as deuterium and contains one proton and one neutron in the nucleus. Deuterium is not radioactive, and does not represent a significant toxicity hazard. Water enriched in molecules that include deuterium instead of normal hydrogen is called heavy water. Deuterium and its compounds are used as a non-radioactive label in chemical experiments and in solvents for ^1H -NMR spectroscopy. Heavy water is used as a neutron moderator and coolant for nuclear reactors. Deuterium is also a potential fuel for commercial nuclear fusion.

The ^3H isotope (known as tritium) contains one proton and two neutrons in the nucleus. It is radioactive, decaying into helium-3 (^3He) through beta-decay, and has a half-life of 12.32 years. Tritium (in small amounts) is produced naturally by the interaction of cosmic rays with atmospheric gases; tritium has also been released during testing of nuclear weapons.

The symbols D and T (instead of ^2H and ^3H) are sometimes used for deuterium and tritium, but the corresponding symbol for protium, P, is already in use for phosphorus and thus is not available for protium.

Hydrogen Purification

When the hydrogen content of the refinery gas is greater than 50% by volume, the gas should first be considered for hydrogen recovery, using a membrane or pressure swing adsorption unit. The tail gas or reject gas that will still contain a substantial amount of hydrogen can then be used as steam reformer feedstock. Generally, the feedstock purification process uses three different refinery gas streams to produce hydrogen. First, high-pressure hydrocracker purge gas is purified in a membrane unit that produces hydrogen at medium pressure and is combined with medium pressure off-gas that is first purified in a pressure swing adsorption unit. Finally, low-pressure off-gas is compressed, mixed with reject gases from the membrane and pressure swing adsorption units, and used as steam reformer feed.

Various processes are available to purify the hydrogen stream, but since the product streams are available as a wide variety of composition, flows, and pressures, the best method of purification will vary. And there are several factors that must also be taken into consideration in the selection of a purification method. These are: (i) hydrogen recovery, (ii) product purity, (iii) pressure profile, and (iv) reliability. Cost, an equally important parameter, is not considered here since the emphasis is on the technical aspects of the purification process.

Wet scrubbing systems, particularly amine or potassium carbonate systems, are used for removal of acid gases such as hydrogen sulfide or carbon dioxide. Most systems depend on chemical reaction and can be designed for a wide range of pressures and capacities. They were once widely used to remove carbon dioxide in steam reforming plants, but have generally been replaced by pressure swing adsorption units except where carbon monoxide is to be recovered. Wet scrubbing is still used to remove hydrogen sulfide and carbon dioxide in partial oxidation plants.

Wet scrubbing systems remove only acid gases or high-boiling hydrocarbon derivatives, but they do not methane or other hydrocarbon gases, hence have little influence on product purity. Therefore, wet scrubbing systems are most often used as a pretreatment step, or where a hydrogen-rich stream is to be desulfurized for use as fuel gas.

See also: Gas Cleaning.

Hydrogenation and Hydrolysis Processes

The reduction of carbonyl sulfide, carbon disulfide, sulfur dioxide, and sulfur vapor in Claus tail gas to hydrogen sulfide is necessary when sulfur recovery of 99.9+% is required. Usually, the sulfur recovery level is set by the allowable emissions of sulfur from the tail gas incinerator. In addition, the reduction of carbonyl sulfide is done on raw synthesis gas when the downstream acid gas removal process is unable to remove carbonyl sulfide to a sufficient extent to meet sulfur emissions regulations from combustion of the cleaned fuel gas. These sulfur compounds are reduced to hydrogen sulfide by hydrogenation or by hydrolysis, at a raised temperature, over a catalytic bed.

In these processes, elemental sulfur and sulfur dioxide are reduced mainly via hydrogenation, while carbonyl sulfide and carbon disulfide are mainly hydrolyzed to hydrogen sulfide. Sulfur and sulfur dioxide are virtually completely converted to hydrogen sulfide when an excess of hydrogen is present.

The hydrogen can be supplied from an outside source, can already be in the Claus tail gas, or obtained by partial oxidation of the fuel gas in a furnace. The tail gas is preheated to the reactor temperature by an in-line burner that combusts fuel gas directly into the tail gas. The same burner can also be used to supply the needed hydrogen by partial combustion of the fuel gas.

When oxygen enrichment is used in the Claus plant, there is often sufficient hydrogen in the tail gas to carry out the reduction without an outside hydrogen source. There is usually sufficient water vapor in the Claus tail gas for the hydrolysis reactions.

The SCOT (Shell Claus Off-gas Treating) process was developed in the early 1970s and consists of a combination of a catalytic hydrogenation/hydrolysis step and an amine scrubbing unit. The hydrogenation/hydrolysis of the sulfur compounds in the tail gases from the Claus unit has already been covered above.

The early SCOT units consisted of a hydrogenation/hydrolysis reactor and a conventional amine unit. The Claus tail gas, after being reduced in the reactor, is cooled in a quench column and scrubbed by a Sulfinol solution. The clean tail gas goes to a Claus incinerator, and the acid gas-rich solution is regenerated in a stripping column. The acid gas off the top of the stripper is recycled back to the Claus plant for further conversion of the hydrogen sulfide. The absorber is operated at near atmospheric pressure, and the amine solvent is not highly loaded with acid gases. Because the solution is not highly loaded, unlike high pressure operation, there is no need for an intermediate flash vessel and the loaded solution goes directly to a stripper.

Early SCOT units used diisopropanolamine in the Sulfinol (Sulfinol-D) solution. Methyl diethanolamine-based Sulfinol (Sulfinol-M) was used later to enhance hydrogen sulfide removal and to allow for selective rejection of carbon dioxide in the absorber.

To achieve the lowest possible hydrogen sulfide content in the treated gas, the Super-SCOT configuration was introduced. In this version, the loaded Sulfinol-M solution is regenerated in two stages. The partially stripped solvent goes to the middle of the absorber, while the fully stripped solvent goes to the top of the absorber. The solvent going to the top of the absorber is cooled below that used in the conventional SCOT process.

The SCOT process can be configured in various ways. For example, it can be integrated with the upstream acid gas removal unit if the same solvent is used in both units. Another configuration has been used to cascade the upstream gas cleanup with the SCOT unit. A hydrogen sulfide-lean acid gas from the upstream gas treating unit is sent to a SCOT process with two absorbers. In the first absorber, the hydrogen sulfide-lean acid gas is enriched, while the second absorber treats the Claus tail gas. A common stripper is used for both SCOT absorbers and, in this latter configuration, different solvents could be used in both the upstream and the SCOT units.

Hydrogen Energy

Hydrogen is the simplest element on earth. An atom of hydrogen has only one proton and one electron. Hydrogen gas is a diatomic molecule—each molecule has two atoms of hydrogen (H_2). At standard temperature and pressure, hydrogen exists as a gas. It is colorless, odorless, tasteless, and lighter (less dense) than air. Like electricity, hydrogen is an energy carrier (not an energy source), meaning it can store and deliver energy in an easily usable form. Although abundant on earth as an element, hydrogen combines readily with other elements and is almost always found as part

of some other substance, such as water (H_2O), or hydrocarbon derivatives like natural gas (which consists primarily of methane, CH_4). Hydrogen is also found in biomass, which includes all plants and animals.

Fuel cells use hydrogen to create electricity, with only heat and water as by-products. When used to power a vehicle, the only output from the tailpipe is water vapor—no greenhouse gas or criteria emissions. To realize the environmental benefits of hydrogen, however, consideration must be given to the full fuel cycle (also called “well-to-wheels”) – from energy source to hydrogen production to end-use. Producing hydrogen from renewable sources or nuclear energy yields virtually zero greenhouse gas emissions. Hydrogen produced from coal, when combined with capture and sequestration of the by-product carbon dioxide, also results in virtually no greenhouse gas emissions.

Thermal processes use the energy in resources including natural gas, coal, or biomass to produce hydrogen. Some “thermochemical” processes use heat combined with closed chemical cycles to produce hydrogen from feedstocks such as water. Thermal processes include (i) natural gas reforming – natural gas reforming natural gas contains methane (CH_4) that can be used to produce hydrogen via thermal processes, (ii) gasification of hydrocarbonaceous feedstocks, (iii) renewable liquid fuel reforming, (iv) high temperature water splitting, and (v) partial oxidation of hydrocarbonaceous feedstocks. Hydrogen can also be produced via steam reforming of fuels including gasoline, propane, and ethanol; however, approximately 95% of the hydrogen produced in the United States is produced by steam-methane reforming, in which high-temperature steam ($700 - 1,000^\circ\text{C}$, $1,830^\circ\text{F}$) is used to produce hydrogen from a methane source such as natural gas. The methane reacts with steam under 45 to 375 psi pressure in the presence of a catalyst to produce hydrogen, carbon monoxide, and a relatively small amount of carbon dioxide. The carbon monoxide and steam are then reacted using a catalyst to produce carbon dioxide and more hydrogen – the water-gas shift reaction. In the final process step – the pressure-swing adsorption step – carbon dioxide and other impurities are removed from the gas stream, leaving essentially pure hydrogen.

In the partial oxidation process, the methane and other hydrocarbon derivatives in natural gas are reacted with a limited amount of oxygen (typically from air) that is not enough to completely oxidize the hydrocarbon derivatives to carbon dioxide and water. With less than the stoichiometric amount of oxygen available for the reaction, the reaction products contain primarily hydrogen and carbon monoxide (and nitrogen, if the reaction is carried out with air rather than pure oxygen), again with a relatively small amount of carbon dioxide and other compounds. The product gas is often referred to as synthesis gas (or syngas) from which hydrogen can be separated for use. Unlike steam reforming, which is an endothermic process that requires heat, partial oxidation is an exothermic process that gives off heat. Typically, it is much faster than steam reforming and requires a smaller reactor vessel. As illustrated in the chemical reactions (see sidebar), partial oxidation initially produces less hydrogen per unit of the input fuel than is obtained by steam reforming of the same fuel. As in steam reforming, to maximize the amount of hydrogen produced, partial oxidation usually includes a water-gas shift reaction to generate additional hydrogen from the oxidation of carbon monoxide to carbon dioxide by reaction with water (steam).

Biomass includes crop or forest residues; special crops grown specifically for energy use like switchgrass or willow trees; and organic municipal solid waste. Because biomass resources often consume carbon dioxide in the atmosphere as part of their natural growth processes, producing hydrogen through biomass gasification may release near-zero net greenhouse gases.

Electrolytic processes use electricity to split water into hydrogen and oxygen in a unit called an electrolyzer. Like fuel cells (see page 25), electrolyzers consist of an anode and a cathode separated by an electrolyte. The electrolyte determines the type of electrolyzer and its operating conditions. In a polymer electrolyte membrane (PEM) electrolyzer. Water at the anode reacts to form oxygen and positively charged hydrogen ions (protons) and electrons that flow through the external circuit. The hydrogen ions move across the polymer electrolyte membrane to the cathode. At the cathode, hydrogen ions combine with electrons from the external circuit to form hydrogen gas. Alkaline electrolyzers are similar to polymer electrolyte membrane electrolyzers, but instead use an alkaline solution (of sodium or potassium hydroxide) as the electrolyte. Both PEM and alkaline electrolyzers operate at relatively low temperatures – 80 to 100°C (176 to 212°F) and 100 to 250°C (212 to 480°F), respectively.

Electricity can be generated using renewable resources such as wind, solar, geothermal, or hydro-electric power. Hydrogen production via “renewable electrolysis” offers opportunities for synergy with variable power generation. For example, though the cost of wind power has continued to drop, the inherent variability of wind impedes its widespread use. Co-production of hydrogen and electric power could be integrated at a wind farm, allowing flexibility and the ability to shift production to match the availability of resources with the operational needs and market factors of the system.

Biomass resources, when converted to ethanol, bio-oils, or other liquid fuels, can be transported at relatively low cost to the point of use and reformed onsite to produce hydrogen. Reforming renewable liquids is similar to reforming natural gas. The liquid fuel is reacted with steam at high temperatures in the presence of a catalyst to produce a reformat gas composed of mostly hydrogen and carbon monoxide. Reacting the carbon monoxide with steam in a water-gas shift reaction produces additional hydrogen and carbon dioxide.

Since renewable liquids consist of higher molecular weight constituents, they can be somewhat more difficult to reform than the methane in natural gas. Better catalysts will improve hydrogen yields and selectivity. And like natural gas reforming, operation, maintenance, and capital equipment costs must be reduced and the energy efficiency must be improved for the hydrogen produced to be cost-competitive with conventional fuels.

Hydrogen Sulfide

Hydrogen sulfide (Table H-5) is the chemical compound with the formula H_2S . It is a colorless chalcogen hydride gas with the characteristic foul odor of rotten eggs. It is poisonous, corrosive, and flammable.

Table H-5 General properties of hydrogen sulfide.

Property	Data
Formula	H_2S
Molar mass	34.1 g/mol
Boiling point	-60°C (-76°F)
Melting point	-85.5°C (-121.9°F)
Soluble in	water and alcohol

The thermal decomposition of biomass feedstocks can produce hydrogen sulfide (as well as hydrogen cyanide) which can be removed by alkaline scrubbing of coal gas by conversion to nonvolatile species:

Each process is reversible (by neutralization), which facilitates recovery of hydrogen cyanide and hydrogen sulfide from the scrubber solutions.

Hydrogen sulfide can be removed from gas streams at relatively high temperatures using solid sorbents. The process (at approximately 540°C ; 1005°F) involves the reaction of hydrogen sulfide with hydrogen in the presence of iron oxide:

Ensuing regeneration of the sorbent is accomplished by high-temperature reaction with oxygen to yield a concentrated stream of sulfur dioxide and regenerated iron oxide.

Hydrogen Sulfide – Control

The systems for removing hydrogen sulfide that are available to be used for oil shale operations can generally remove at least 98% of this pollutant. Such processes will probably be applied to gas streams from retorting and upgrading

operations. The Beavon Process, Claus Process, IFP Process, SCOT Process, Selexol Process, and Stretford Process are used as examples.

In the Beavon process, the tail gas from a Claus plant is mixed with hot combustion gases and passed through a catalyst where all the sulfur compounds are converted to hydrogen sulfide. The hydrogen sulfide-rich gas is cooled by a slightly alkaline buffer solution and then treated in a Stretford unit. The Beavon process is also adversely affected by high concentrations of carbon dioxide in the feed stream. Its use in oil shale plants would require adaptations similar to those needed for the SCOT process.

The Claus process, which is the oldest and best known method for recovering sulfur from streams that contain both hydrogen sulfide and sulfur dioxide, has several variations. With a feed stream containing only hydrogen sulfide, the required sulfur dioxide is obtained by oxidizing part of the hydrogen sulfide to sulfur dioxide by burning it in air, and then mixing the combustion products with the feed stream. The hydrogen sulfide and sulfur dioxide are then reacted with each other in a series of converters to produce elemental sulfur, which is removed by condensation. The feed stream must have a relatively high concentration of sulfur compounds in order to achieve high conversion efficiency with reasonable equipment size. This process has problems with both maintenance and downtime. Thus backup units are often needed. Problems arise from sulfur condensation in the supply and product pipelines. The tail gas (treated gas) from a Claus plant still contains fairly sizable concentrations of hydrogen sulfide to sulfur dioxide and can be recirculated, mixed with a large volume of stack gas and released, or treated in other systems. In oil shale plants, it is likely that the Claus plant effluent would require further treatment before being released using processes such as the SCOT process, the Beavon process, and the IFP process.

In the SCOT process (Shell Claus Offgas Treating process), the offgas is heated with a reducing gas such as hydrogen, and the mixture is passed through a cobalt-molybdate catalyst bed where all the sulfur compounds are reduced to hydrogen sulfide. The gas is then sent through an absorber where the hydrogen sulfide is dissolved and concentrated. The concentrated hydrogen sulfide is liberated from the absorbing medium by heating and is returned to the Claus plant. The SCOT process is adversely affected by high concentrations of carbon dioxide, and since gaseous emissions from oil shale processing are expected to be rich in carbon dioxide, higher rates of recycling, more complete fuel combustion, and perhaps steam injection to dissolve the carbon dioxide may be necessary.

The IFP process (Institut Français du Pétrole process) uses the same basic reaction as the Claus process except that it takes place in a liquid rather than a gaseous phase. The liquid is a polyalkylene glycol with a 5% concentration of a glycol ester catalyst. Both hydrogen sulfide and sulfur dioxide are very soluble in this liquid, and efficient conversion to sulfur results. The most important operating variable is the hydrogen sulfide/sulfur dioxide, which must be at least 2. The process is flexible and can accommodate wide changes in contaminant concentrations while maintaining constant conversion rates. Also, because the gases can be treated at higher temperatures than in other processes, heat losses are reduced.

The Selexol process is a physical absorption processes in which the hydrogen sulfide is dissolved in a solvent and subsequently recovered. The solvent is recycled. The earliest process, a simple water wash, was inefficient because hydrogen sulfide is not very soluble in water. Modern processes use solvents in which it is more readily dissolved. Absorption processes are usually used for treating high-pressure gases and for reducing the concentrations of hydrogen sulfide and other sulfur compounds to extremely low levels. These processes involve the selective absorption of hydrogen sulfide from gases containing carbon dioxide. This produces a hydrogen sulfide-rich stream that can be processed in a Claus plant. Absorption processes can also remove sulfur compounds, such as carbonyl sulfide, carbon disulfide, mercaptans, and thiophenes, which cannot be processed in a Stretford unit. Because of its low cost and simplicity, the Selexol process is a good candidate for use in oil shale plants.

In the Stretford process, the gas stream is scrubbed in an absorption tower with a solution containing sodium carbonate, sodium metavanadate, and anthraquinone disulfonic acid (ADA). Reduction of the metavanadate with hydrogen sulfide in solution causes sulfur to precipitate. The metavanadate is regenerated by oxidation with the anthraquinone disulfonic acid, and the reduced anthraquinone disulfonic acid is then regenerated by being oxidized in an air stream. The process was originally developed for coal-gas treatment, but it has been used for many other purposes in a number of plants. Any carbonyl sulfide (COS) and carbon disulfide (CS₂) that may also be in the gas stream would not be removed in this process, and their presence would interfere with hydrogen sulfide removal. Therefore, before hydrogen sulfide removal, the gas stream would need to be pretreated to remove these compounds.

Hydrogen Sulfide Conversion

The disposition of hydrogen sulfide is an issue with many gas processing operations. Burning hydrogen sulfide as a fuel gas component or as a flare gas component is precluded by safety and environmental considerations since one of the combustion products is the highly toxic sulfur dioxide (SO_2), which is also toxic.

As described above, hydrogen sulfide is typically removed from gas streams through an olamine process after which application of heat regenerates the olamine and forms an acid gas stream (also called the tail gas stream). Following from this, the acid gas stream is treated to convert the hydrogen sulfide to elemental sulfur and water. The conversion process utilized in most modern refineries is the Claus process, or a variant thereof.

The Claus process involves combustion of approximately one-third of the hydrogen sulfide to sulfur dioxide and then reaction of the sulfur dioxide with the remaining hydrogen sulfide in the presence of a fixed bed of activated alumina, cobalt molybdenum catalyst resulting in the formation of elemental sulfur:

Different process flow configurations are in use to achieve the correct hydrogen sulfide/sulfur dioxide ratio in the conversion reactors.

Overall, conversion of 96 to 97% of the hydrogen sulfide to elemental sulfur is achievable in a Claus process. If this is insufficient to meet air quality regulations, a Claus process tail gas treater is utilized to remove essentially the entire remaining hydrogen sulfide in the tail gas from the Claus unit. The tail gas treater may employ a proprietary solution to absorb the hydrogen sulfide followed by conversion to elemental sulfur.

The SCOT (Shell Claus Off-gas Treating) unit is also used to treat tail gas and uses a hydrotreating reactor followed by amine scrubbing to recover and recycle sulfur, in the form of hydrogen, to the Claus unit). In the process, tail gas (containing hydrogen sulfide and sulfur dioxide) is contacted with hydrogen and reduced in a hydrotreating reactor to form hydrogen sulfide and water. The catalyst is typically cobalt/molybdenum on alumina. The gas is then cooled in a water contractor. The hydrogen sulfide-containing gas enters an amine absorber which is typically in a system segregated from the other refinery amine systems. The purpose of segregation is two-fold, and that is (i) the tail gas treater frequently uses a different amine than the rest of the plant, and (ii) the tail gas is frequently cleaner than the refinery fuel gas (in regard to contaminants), and segregation of the systems reduces maintenance requirements for the SCOT unit. Amines chosen for use in the tail gas system tend to be more selective for hydrogen sulfide and are not affected by the high levels of carbon dioxide in the off-gas.

The hydrotreating reactor converts sulfur dioxide in the off-gas to hydrogen sulfide that is then contacted with a Stretford solution (a mixture of a vanadium salt, anthraquinone disulfonic acid, sodium carbonate, and sodium hydroxide) in a liquid-gas absorber. The hydrogen sulfide reacts stepwise with sodium carbonate and the anthraquinone sulfonic acid to produce elemental sulfur, with vanadium serving as a catalyst. The solution proceeds to a tank where oxygen is added to regenerate the reactants. One or more froth or slurry tanks are used to skim the product sulfur from the solution, which is recirculated to the absorber.

Other tail gas treating processes include (i) caustic scrubbing, (ii) polyethylene glycol treatment, (iii) Selectox process, and (iv) sulfite/bisulfite tail gas treating.

See also: Gas Cleaning, Hydrogen Sulfide, Hydrogen Sulfide Hydrogen Sulfide Removal.

Hydrogen Sulfide Removal

Hydrotreating creates hydrogen sulfide gas that requires disposal. The usual process is a two-stage operation involving (i) the removal of the hydrogen sulfide from the gas stream from the hydrocarbon stream, and (ii) the conversion of the hydrogen sulfide in a gas stream to elemental sulfur.

Removal of the hydrogen sulfide from the hydrocarbon stream can be accomplished by a number of different chemical processes of which the most widely used is solvent extraction using diethanolamine (DEA). A mixture of diethanolamine and water trickles down a contactor containing with trays or packing that distribute the liquid, while the gas stream containing the hydrogen sulfide enters at the base of the contactor. The diethanolamine selectively absorbs the hydrogen sulfide after which the hydrogen sulfide-rich (fat) diethanolamine is then fractionated to separate the hydrogen sulfide that is sent to a sulfur recovery plant and the stripped (lean) diethanolamine recycled.

The conversion of hydrogen sulfide to sulfur is accomplished by means of the Claus process, and, although there are variations on the process, most options use a two-stage, split-stream process. In the first stage, part of the hydrogen sulfide stream is burned in a furnace in a limited supply of oxygen to produce not only sulfur dioxide and water but also sulfur.

The remainder of the hydrogen sulfide is mixed with the combustion products and passed over a catalyst. The hydrogen sulfide reacts with the sulfur dioxide to form sulfur and water:

Thus, Claus plants convert approximately 90% to 93% of the hydrogen sulfide to sulfur, and removal of the remaining sulfur can be achieved by use of more advanced processes, such as (for example) the Stretford process.

Hydrogeology

Hydrogeology is the branch of science that deals with the occurrence and movement of subterranean water, and it is a subdivision of the science of hydrology that deals with the water beneath the surface of the Earth. It is interdisciplinary in scope in that it involves the application of the physical, biological, and mathematical sciences. Because hydrogeology deals with the occurrence and movement of water in an almost infinitely complex subsurface geologic environment, it is, in its most advanced state, one of the most complex of the sciences. On the other hand, many of the basic principles and methods of hydrogeology can be understood readily and used in the solution of groundwater problems.

The relevance of the science of hydrogeology is becoming more relevant where overexploitation, declining groundwater levels, and groundwater quality issues are affecting the lives of most of the population. Thus, good understanding and successful application of this science by the practitioners is of critical importance to the welfare of the environment.

Hydrokinetic Energy

Hydrokinetic energy is the energy generated by the movement of a body of water. The Earth's tides, waves, ocean currents, and free-flowing rivers contain an untapped, powerful, highly-concentrated and clean energy resource. Traditional hydropower (river dams and conduits) is also produced by moving water. A variety of hydrokinetic energy sources are described below.

This class of renewable energy technology is being strongly recognized as a unique and unconventional solution that falls within the realms of both in-land water resource and marine energy. In contrast to conventional hydroelectric plants, where an artificial water-head is created using dams or penstocks (for large-hydro and micro-hydro, respectively), hydrokinetic converters are constructed without significantly altering the natural pathway of the water stream. With regard to ocean power utilization, these technologies can be arranged in multi-unit array that would

extract energy from tidal and marine currents as opposed to tidal barrages where stored potential energy of a basin is harnessed.

In-stream hydrokinetic projects generate electricity directly from the flow of water in rivers, inland waterways, irrigation canals, and other man-made conduits. Energy-generating mechanisms may be placed as individual units or in arrays. They may be submerged, floating, or tethered to existing structures like bridge abutments or other in-water infrastructure. Some are placed downstream from existing hydropower projects.

In-stream hydrokinetic projects generate energy from the horizontal flow of water. These energy-generating projects use a variety of technologies, including the following: (i) horizontal axis turbines, (ii) vertical axis turbines, and (iii) helical turbines that may be either vertical or horizontal. As the water current passes through the turbine (rotor fan), the turbine rotates on a shaft connected to the generator. The rotational speed is proportional to the velocity of the fluid.

Horizontal axis turbines may look much like wind turbines, and they extract kinetic energy from the moving water in the same way that wind turbines extract energy from moving air. Sometimes, the rotor is enclosed inside a duct (often funnel-shaped) to concentrate the flow past the turbine. This may allow operation over a greater range of current velocities and generate more electricity per unit of rotor area. In vertical axis turbines, the axis of the rotor is oriented perpendicular to the flow. Vertical axis turbines may take many different forms and also may be enclosed within a duct.

The ocean produces two different types of energy which are (i) the thermal energy from the heat of the Sun, and (ii) the mechanical energy derived from the tides and waves. Tides are driven primarily by the gravitational pull of the moon, and waves are driven primarily by winds. Tides and waves are therefore intermittent sources of energy, while ocean thermal energy (from the sun) is fairly constant. The electricity conversion of both tidal and wave energy usually involves mechanical devices.

Wave power devices extract energy directly from the surface motion of powerful ocean waves or from pressure fluctuations below the surface. A variety of technologies have been proposed to capture wave energy. Some of the more promising designs are now being tested at commercial scales. Wave technologies have been designed for near-shore, offshore, and far offshore locations. All wave energy technologies are intended to be installed at or near the water's surface, in waters more than 40 meters deep. These technologies differ in their orientation to the waves with which they are interacting and the manner in which they convert wave energy into electricity.

Tidal and ocean current energy can be exploited by the following: (i) building semi-permeable barrages (dam-like structures) across estuaries with a high tidal range, or (ii) harnessing offshore tidal streams. Unlike wind and waves, tidal and ocean currents are fairly predictable. During high tides, barrages allow tidal waters to fill an estuary through sluices which then close when the tide begins to fall. Once the tide is low enough, the stored water is released at pressure through turbines.

Tidal energy may be harnessed using offshore underwater devices similar to wind turbines. Submerged rotating devices capture energy through the processes of hydrodynamic lift or drag. These devices consist of rotor blades, a generator for converting the rotational energy into electricity, and a means for transporting the electrical current to the on-shore electrical grid. Submerged turbines can have either a horizontal or vertical axis of rotation. Mechanisms such as posts, cables, or anchors are required to keep the turbines stationary relative to the tidal currents. Prototype horizontal axis turbines, similar to wind turbines, have been built and tested. Vertical axis turbine designs have been proposed, with some designs resembling egg beaters.

Turbines may be anchored to the ocean floor in a variety of ways. They may be tethered with cables, using the relatively constant current interacting with the turbine to maintain location and stability. Imagine an underwater kite flying, where the kite is the upright turbine and the kite flyer is the anchor. The system may also include concentrators (or shrouds) around the blades to increase the flow and power output from the turbine. Another proposed design is mooring a barge in the current stream with a large cable loop to which water-filled parachutes are fastened. The parachutes would be pushed by the current and then closed on their way back, forming a loop similar to a large horizontal waterwheel. In large areas with powerful currents, it may be possible to install water turbines in groups or clusters to create a "marine energy facility" (similar to a wind energy facility). Turbine spacing would be determined based on wake interactions and maintenance needs.

Hydrokinetic Power Generation

Hydrokinetic energy converters can tap into three types of resources: (i) inland rivers, (ii) tidal estuaries and channels, and (iii) ocean currents.

Axial-flow systems

The vast majority of the hydrokinetic energy converter system are lift-based, axial-flow, tidal turbines. Drag-based systems typically have lower efficiencies compared to lift-based systems. However, drag-based systems can be useful in extracting energy from flows with exceptional amounts of debris, which is an important consideration for some sites. Lift-based, axial-flow turbines use the same principles as aircraft wings, propellers, and wind turbines. The blades of a lift-based turbine are composed of two-dimensional hydrofoil cross sections.

Cross-flow systems

Cross-flow turbines rely on the same principles as lift-based axial flow turbines to develop a pressure differential across blade-sections. However, cross-flow systems orient the axis of rotation normal to the freestream (versus parallel to the free stream for axial-flow systems). Therefore, as across-flow turbines rotate, the angle of attack of each blade varies cyclically. The cyclical variation of the angle of attack creates cyclical blade loading, which increases the fatigue experienced by the blades. Much of the cyclical loading can be alleviated by using helical instead of straight blades.

Though cross-flow turbines are generally less efficient than axial-flow turbines, they do have some distinct advantages: cross-flow turbines can have a rectangular cross section, which allows them to be more efficiently packed in arrays than circular-cross-section axial-flow turbines. Another benefit is the ability to generate power from any flow direction that is perpendicular to the axis, which is extremely advantageous in a tidal flow.

Oscillating systems

Oscillating systems using flapping foils tend to suffer from a complex control system, which is necessary to maintain the wing's optimal angle of attack to create enough lift for power production. The control system is also required to overcome the pitching moment of the wing and reverse the direction of oscillation. The most successful oscillating system uses vortex-induced vibrations to generate energy. Vortex-induced vibrations occur due to the periodic shedding of vortices in the wake of a bluff body.

Hydrologic Cycle

The term hydrologic cycle refers to the continuous movement of water above, on, and below the surface of the Earth. The concept of the hydrologic cycle is central to an understanding of groundwater supplies. Although the hydrologic cycle has neither a beginning nor an end, it is convenient to discuss the principal features by starting with evaporation from vegetation, from exposed moist surfaces including the land surface and from the ocean.

The Sun warms the earth and oceans, causing water to evaporate and enter the air. Plants also release water into the air through a process called transpiration. As this moisture rises, it cools and condenses to form clouds. These clouds release water as precipitation in the form of rain, sleet, hail, and snow. This precipitation is partly intercepted in its downward movement before it falls on the surface from where part of it infiltrates or runs off, while the rest enter lakes and streams directly. All water on the land surface is surface water. Water that infiltrates, fills the space between particles of soil, sand, and rocks in the earth, thus forming groundwater. Groundwater, which flows very slowly, and surface water, which flows quickly, both move toward the oceans. Plants, animals, and people use some water, and some is returned to the air through transpiration. The remainder returns to the oceans where it again evaporates to repeat the hydrologic cycle.

Hydrolysis and Fermentation of Sugar

The use of sugar and starch crops to produce ethanol through fermentation is well known, but has certain limits: The crops has high value for food application, and their sugar yield per hectare is low compared to the most prevalent forms of sugar in nature: cellulose and hemicellulose. The potential of lignocellulosic biomass is therefore considerably larger than crops and starch, and is especially well suited in Northern parts of the world with less Sun radiation.

Pre-treatment is necessary to remove lignin and hemicellulose, reduce cellulose crystallinity, and increase the porosity of the materials. Pre-treatment technologies are diverse and numerous, but might be categorized in four main groups which are (i) physical pretreatment, (ii) pyrolysis, (iii) ozonolysis, and (iv) biological pretreatment.

The different pre-treatments have their specific advantages and disadvantages, and are at different stages of development. The choice of pre-treatment technology heavily influences cost and performance in subsequent hydrolysis and fermentation.

See also: Fermentation, Starch, Steam Explosion.

Hydrolysis – Anaerobic Digestion

Chemically, the term hydrolysis refers to the cleavage of chemical bonds by the addition of water. Cations and anions react with water molecules, altering pH in the process to create cleavage of H–O bonds. Hydrolysis is the first step in the anaerobic digestion process. It is a relatively slow step that can limit the rate of the overall digestion process, especially when solid waste substrates are used; the reaction associated with this step is:

The reaction is catalyzed by homogeneous or heterogeneous acids to yield a fermentable monosaccharide, glucose ($\text{C}_6\text{H}_{12}\text{O}_6$).

The usefulness of this reaction relates to the fact that the glucose can undergo further successive reactions to produce compounds such as formic acid (HCO_2H , also known as methanoic acid), hydroxymethyl furfural ($\text{C}_6\text{H}_6\text{O}_3$, also known as 5-furfural), and levulinic acid ($\text{C}_5\text{H}_8\text{O}_3$, also known as 4-oxopentanoic acid), which are valuable organic compounds used in the manufacture of a variety of other compounds.

See also: Acetogenesis, Acidogenesis, Methanogenesis.

Hydrolysis – Lignocellulosic Materials

Acid hydrolysis of plant lignocellulosic biomass has been known since 1819 – examples are the modified Bergius process (40% HCl) operated during World War II in Germany, and the more recently modified Scholler processes (0.4% H_2SO_4) in the former Soviet Union, Japan, and Brazil. Acid hydrolysis can be performed with several types of acids, including (alphabetically) formic acid, hydrochloric acid, hydrofluoric acid, nitric acid, phosphoric acid, sulfuric acid, and sulfurous acid either in concentrated or diluted form.

Processes involving concentrated acids are operated at low temperature and give high yields (on the order of 90% w/w of theoretical glucose yield), but the large amount of acids used causes problems associated with equipment corrosion and energy-demanding acid recovery.

The main advantage of dilute acid hydrolysis is the relatively low acid consumption. However, high temperatures are required to achieve acceptable rates of conversion of cellulose to glucose, and high temperatures also increase the rates of hemicellulose sugar decomposition and equipment corrosion. Sugar degradation products can also cause inhibition in the subsequent fermentation stage. The maximum yield of glucose is obtained at high temperature and short residence time, but even under these conditions, the glucose yield is only between 50% and 60% of the theoretical value.

A two-stage process has been developed to decrease sugar degradation. In the first hydrolysis stage, the relatively easily hydrolyzed hemicellulose is released under mild conditions. This enables the second acid hydrolysis step to proceed under harsher conditions without degrading the hemicellulose sugars to furfural, hydroxymethyl-furfural, and other degradation products. Using a two-stage dilute acid hydrolysis process, recovery yields of as much as 70 to 98% of the xylose, galactose, mannose, and arabinose from softwood is possible. However, the yield of glucose was still low at 50%.

See also: Acid Hydrolysis, Concentrated Acid Hydrolysis.

Hydropower

The energy of falling water and running water can be utilized to provide *water power* or *hydropower*, which is the form of renewable energy derived from the gravitational force of falling or flowing water harnessed for useful purposes. Since ancient times, hydropower has been used for irrigation and the operation of various mechanical devices, such as watermills, sawmills, textile mills, dock cranes, domestic lift, and power houses.

Since the early twentieth century, the term hydropower has been used almost exclusively in conjunction with the modern development of hydroelectric power, which allowed use of distant energy sources. Hydroelectricity is the term referring to electricity generated by hydropower, the production of electrical power through the use of the gravitational force of falling or flowing water. Another method used to transmit energy involves a *trompe*: a water-powered gas compressor, commonly used before the advent of the electric-powered compressor, which is somewhat like an airlift pump working in reverse. A *trompe* produces compressed air from falling water. Compressed air could then be piped to power other machinery at a distance from the waterfall.

Understanding the water cycle is important to understanding hydropower. The water cycle has three steps: (i) solar energy heats water on the surface of rivers, lakes, and oceans, which causes the water to evaporate, (ii) water vapor condenses into clouds and falls as precipitation – rain and snow, and (iii) precipitation collects in streams and rivers, which empty into oceans and lakes, where it evaporates and begins the cycle again.

The amount of precipitation that drains into rivers and streams in a geographic area determines the amount of water available for producing hydropower. Seasonal variations in precipitation and long-term changes in precipitation patterns, such as droughts, can have large effects on the availability of hydropower production.

Because the source of hydroelectric power is water, hydroelectric power plants are usually located on or near a water source. The volume of the water flow and the change in elevation – or fall, and often referred to as *head* – from one point to another determine the amount of available energy in moving water. In general, the greater the water flow and the higher the head, the more electricity a hydropower plant can produce. At hydropower plants, water flows through a pipe, or *penstock*, then pushes against and turns blades in a turbine to spin a generator to produce electricity.

Run-of-the-river systems are systems where the force of the river's current applies pressure on a turbine. The facilities may have a *weir* in the water course to divert water flow to hydro turbines. *Storage systems* are systems where water accumulates in reservoirs created by dams on streams and rivers and is released through hydro turbines as needed to generate electricity. Most U.S. hydropower facilities have dams and storage reservoirs.

Pumped-storage hydropower facilities are a type of hydroelectric storage system where water is pumped from a water source up to a storage reservoir at a higher elevation and is released from the upper reservoir to power hydro turbines located below the upper reservoir. The electricity for pumping may be supplied by hydro turbines or by other types of power plants including fossil fuel or nuclear power plants. They usually pump water to storage when electricity demand and generation costs, and/or when wholesale electricity prices are relatively low and release the stored water to generate electricity during peak electricity demand periods when wholesale electricity prices are relatively high. Pumped-storage hydroelectric systems generally use more electricity to pump water to the upper water storage reservoirs than they produce with the stored water. Therefore, pumped-storage facilities have net negative electricity generation balances.

Hydroprocessing

Hydroprocessing is a term often equally applied to hydrotreating and to hydrocracking – also often collectively applied to both types of processes.

The use of hydrogen in thermal processes uses the principle that the presence of hydrogen during a thermal reaction of a petroleum feedstock will terminate many of the coke-forming reactions and enhance the yields of the lower-boiling products. Hydrogenation processes for the conversion of various feedstocks may be classified as (i) destructive hydrogenation and (ii) nondestructive hydrogenation.

Destructive hydrogenation (hydrogenolysis or hydrocracking) is characterized by the conversion of the higher-molecular-weight constituents in a feedstock to lower-boiling products. Such treatment requires severe processing conditions and the use of high hydrogen pressures to minimize polymerization and condensation reactions that lead to coke formation.

Nondestructive or simple hydrogenation is generally used for the purpose of improving product quality without appreciable alteration of the boiling range. Mild processing conditions are employed so that only the more unstable materials are attacked. Nitrogen, sulfur, and oxygen compounds undergo reaction with the hydrogen to remove ammonia, hydrogen sulfide, and water, respectively. Unstable compounds which might lead to the formation of gums, or insoluble materials, are converted to more stable compounds.

Hydroshear Emulsification

Hydroshear emulsification can be used to produce emulsions of diesel-alcohol. However, the emulsion can only remain stable for 45 seconds and, 12% v/v alcohol (energy basis) is the maximum percentage. In the hydro-shear emulsifier (sometimes referred to as a homogenizer), the premixed liquids are pumped into a cylindrical chamber at relatively low pressure. The liquids enter the chamber through a tangential port at its center and exit via two cone-shaped discharge nozzles at the ends of the chamber and accelerate to a high velocity as they enter the chamber, spread out to cover the full width of the chamber wall and flow toward the center, rotating in ever-decreasing circles. High shear develops between the adjacent layers of liquid, destabilizing the large droplets of the internal phase. In the center of the cylinder, a zone of low pressure develops and cavitation, ultrahigh frequency vibration, and shock waves occur which all contribute to the breakup of the droplets and the formation of an emulsion.

Hydrothermal Upgrading

The hydro thermal upgrading process (HTU process) converts biomass in the presence of water. Liquefaction takes place at moderate temperatures at, high pressure with the addition of hydrogen. The interest in liquefaction is low because the reactors and fuel feeding systems are more complex and more expensive than for pyrolysis processes.

In the hydrothermal upgrading process (HTU process), biomass is treated for 5-20 min in water at temperatures of 300 to 360°C (570 to 650°F) and pressure of 1,500 to 2,650 psi. As a result, most of the oxygen is removed from the biomass feedstock, mainly as carbon dioxide and – and to a lesser extent – as water. The product obtained is a high-boiling organic liquid with 10 to 20% oxygen content on weight basis. The claimed thermal efficiency of the conversion process is 75 to 80%. The properties of the HTU product (biocrude) resemble those of crude oil (Table H-6).

Table H-6 Feedstocks and products for the hydrothermal upgrading process.

Feedstocks	Descriptors
Biomass	Agricultural residue Domestic residue Municipal solid waste Sewage sludge Wood and forest waste
Process parameters	Reaction medium: water Temperature: 300-350°C (570-660°F) Pressure: 1,700 to 2,600 psi Residence time: 5-20 minutes (feedstock dependent)
Process chemistry	Decarboxylation Dehydration Depolymerization Hydrodeoxygenation Hydrogenation
Products (% w/w on feedstock)	Bio-oil (biocrude): 45 Gas: 25 Water-soluble organic products: 10 Other: 20

In principle, biocrude could be fed into an entrained flow gasifier, similar to pyrolysis slurry. Nevertheless, it is more often considered for further upgrading via catalytic hydrodeoxygenation (HDO) to middle distillate products (kerosene, diesel) and refinery feedstock.

The main advantage of the hydrothermal upgrading process is its suitability for wet biomass. Nonetheless, considering that the entrained flow gasification releases as by-product a lot of waste heat, which anyhow has to find useful application, this advantage becomes less important.

Hydrotreating

Hydrotreating is a catalytic hydrogenation process used to remove approximately 90% of contaminants such as nitrogen, sulfur, oxygen, and metals from liquid petroleum fractions. These contaminants, if not removed from the petroleum fractions as they travel through the refinery processing units, can have detrimental effects on the equipment, the catalysts, and the quality of the finished product. Typically, hydrotreating is done prior to processes such as catalytic reforming so that the catalyst is not contaminated by untreated feedstock. Hydrotreating is also used prior to catalytic cracking to reduce sulfur and improve product yields, and to upgrade middle-distillate petroleum fractions into finished kerosene, diesel fuel, and heating fuel oils. In addition, hydrotreating converts olefins and aromatics to saturated compounds.

The increasing importance of hydrosulfurization (HDS) and hydrodenitrogenation (HDN) in petroleum processing in order to produce clean-burning fuels has led to a surge of research on the chemistry and engineering of heteroatom removal, with sulfur removal being the most prominent area of research. Most of the earlier works are focused (i) on catalyst characterization by physical methods, (ii) on low-pressure reaction studies of model compounds having relatively high reactivity, (iii) on process development, or (iv) on cobalt-molybdenum – Co-Mo – catalysts, nickel-molybdenum catalysts – Ni-Mo – or nickel-tungsten – Ni-W – catalysts supported on alumina, often doped by fluorine or phosphorus.

Hydrodesulfurization and demetallization occur simultaneously on the active sites within the catalyst pore structure. Sulfur and nitrogen occurring in residua are converted to hydrogen sulfide and ammonia in the catalytic reactor, and these gases are scrubbed out of the reactor effluent gas stream. The metals in the feedstock are deposited on the catalyst in the form of metal sulfides, and cracking of the feedstock to distillate produces a laydown of carbonaceous material on the catalyst; both events poison the catalyst, and activity or selectivity suffers. The deposition of carbonaceous material is a fast reaction that soon equilibrates to a particular carbon level and is controlled by hydrogen partial pressure within the reactors. On the other hand, metal deposition is a slow reaction that is directly proportional to the amount of feedstock passed over the catalyst.

Basic nitrogen-containing compounds in a feed diminish the cracking activity of hydrocracking catalysts. However, zeolite catalysts can operate in the presence of substantial concentrations of ammonia, in marked contrast to silica-alumina catalysts, which are strongly poisoned by ammonia. Similarly, sulfur-containing compounds in a feedstock adversely affect the noble metal hydrogenation component of hydrocracking catalysts. These compounds are hydrocracked to hydrogen sulfide, which converts the noble metal to the sulfide form. The extent of this conversion is a function of the hydrogen and hydrogen sulfide partial pressures.

Removal of sulfur from the feedstock results in a gradual increase in catalyst activity, returning almost to the original activity level. As with ammonia, the concentration of the hydrogen sulfide can be used to precisely control the activity of the catalyst. Non-noble metal-loaded zeolite catalysts have an inherently different response to sulfur impurities since a minimum level of hydrogen sulfide is required to maintain the nickel-molybdenum and nickel-tungsten in the sulfide state.

The character of the hydrotreating processes is chemically simple since they essentially involve removal of sulfur and nitrogen as hydrogen sulfide and ammonia, respectively:

However, nitrogen is the most difficult contaminant to remove from feedstocks, and processing conditions are usually dictated by the requirements for nitrogen removal.

In general, any catalyst capable of participating in hydrogenation reactions may be used for hydrodesulfurization. The sulfides of hydrogenating metals are particularly used for hydrodesulfurization, and catalysts containing cobalt, molybdenum, nickel, and tungsten are widely used on a commercial basis.

Different rates of reaction may occur with various types and concentrations of metallic compounds. For example, a medium metal-content feedstock will generally have a lower rate of demetallization compared to high-metal content feedstock. And, although individual organometallic compounds decompose according to both first- and second-order rate expressions, for reactor design, a second-order rate expression is applicable to the decomposition of residuum as a whole.

Generally, it is more economical to hydrotreat high-sulfur feedstocks before catalytic cracking than to hydrotreat the products from catalytic cracking. The advantages are (i) the products require less finishing, (ii) the sulfur is removed from the catalytic cracking feedstock, and corrosion is reduced in the cracking unit, (iii) the potential for coke formation during cracking is reduced and higher conversions result, and (iv) the quality of the gas oil fraction is improved.

Although hydrocracking will occur during hydrotreating, attempts are made to minimize such effects, but the degree of cracking is dependent on the nature of the feedstock.

Hydrotreating Catalysts

Hydrotreating catalysts are usually cobalt-molybdenum catalysts and under the conditions whereby nitrogen removal is accomplished, desulfurization usually occurs as well as oxygen removal. Indeed, it is generally recognized

that fullest activity of the hydrotreating catalyst is not reached until some interaction with the sulfur (from the feedstock) has occurred, with part of the catalyst metals converted to the sulfides. Too much interaction may of course lead to catalyst deactivation.

A wide variety of metals are active hydrogenation catalysts; those of most interest are nickel, palladium, platinum, cobalt, iron, nickel-promoted copper, and copper chromite. Special preparations of the first three are active at room temperature and atmospheric pressure. The metallic catalysts are easily poisoned by sulfur-containing and arsenic-containing compounds, and even by other metals. To avoid such poisoning, less effective but more resistant metal oxides or sulfides are frequently employed, generally those of tungsten, cobalt, chromium, or molybdenum.

For hydrotreating of feedstocks that contain appreciable concentrations of sulfur and nitrogen, sulfided nickel-molybdenum (Ni-Mo), nickel-tungsten (Ni-W), or cobalt-molybdenum (Co-Mo) on alumina (γ -Al₂O₃) catalysts are generally used, whereas supported noble metal catalysts have been used for sulfur- and nitrogen-free feedstocks. Catalysts containing noble metals on Y-zeolites have been reported to be more sulfur tolerant than those on other supports. Within the series of cobalt-promoted or nickel-promoted group VI metal (Mo or W) sulfides supported on γ -Al₂O₃, the ranking for hydrogenation is:

Nickel-tungsten (Ni-W) and nickel-molybdenum (Ni-Mo) on Al₂O₃ catalysts are widely used to reduce sulfur, nitrogen, and aromatics levels in petroleum fractions by hydrotreating.

The poisoning effect of nitrogen can be offset to a certain degree by operation at a higher temperature. However, the higher temperature tends to increase the production of material in the methane (CH₄) to butane (C₄H₁₀) range and decrease the operating stability of the catalyst so that it requires more frequent regeneration. Catalysts containing platinum or palladium (approximately 0.5% wet) on a zeolite base appear to be somewhat less sensitive to nitrogen than are nickel catalysts, and successful operation has been achieved with feedstocks containing 40 ppm nitrogen. This catalyst is also more tolerant of sulfur in the feed, which acts as a temporary poison, the catalyst recovering its activity when the sulfur content of the feed is reduced.

On such catalysts as nickel or tungsten sulfide on silica-alumina, isomerization does not appear to play any part in the reaction, as uncracked normal paraffins from the feedstock tend to retain their normal structure. Extensive splitting produces large amounts of low-molecular-weight (C₃-C₆) paraffins, and it appears that a primary reaction of paraffins is catalytic cracking followed by hydrogenation to form iso-paraffins. With catalysts of higher hydrogenation activity, such as platinum on silica-alumina, direct isomerization occurs. The product distribution is also different, and the ratio of low- molecular-weight to intermediate-molecular-weight paraffins in the breakdown product is reduced.

In addition to the chemical nature of the catalyst, the physical structure of the catalyst is also important in determining the hydrogenation and cracking capabilities, particularly for viscous feedstocks. When gas oils and residua are used, the feedstock is present as liquids under the conditions of the reaction. Additional feedstock and the hydrogen must diffuse through this liquid before reaction can take place at the interior surfaces of the catalyst particle.

At high temperatures, reaction rates can be much higher than diffusion rates and concentration gradients can develop within the catalyst particle. Therefore, the choice of catalyst porosity is an important parameter. When feedstocks are to be hydrocracked to liquefied petroleum gas and gasoline, pore diffusion effects are usually absent. High surface area (approximately 300 m²/g) and low-to-moderate porosity (from 12 D pore diameter with crystalline acidic components to 50 D or more with amorphous materials) catalysts are used. With reactions involving high-molecular-weight feedstocks, pore diffusion can exert a large influence, and catalysts with pore diameters greater than 80 D are necessary for more efficient conversion.

Catalyst operating temperature can influence reaction selectivity since the activation energy for hydrotreating reactions is much lower than for hydrocracking reaction. Therefore, raising the temperature in a residuum hydrotreater increases the extent of hydrocracking relative to hydrotreating, which also increases the hydrogen consumption.

The life of a catalyst used to hydrotreat petroleum residua is dependent on the rate of carbon deposition and the rate at which organometallic compounds decompose and form metal sulfides on the surface. Several different metal complexes exist in the asphaltene fraction of the residuum, and an explicit reaction mechanism of decomposition that would be a perfect fit for all of the compounds is not possible. However, in general, terms, the reaction can be described as hydrogen which is (i) dissolved in the feedstock contacting an organometallic compound, (ii) at the surface of the hydrotreating catalyst and producing a metal sulfide, and (iii) producing a hydrocarbon derivative.

Molybdenum sulfide (MoS_2), usually supported on alumina, is widely used in petroleum processes for hydrogenation reactions. It is a layered structure that can be made much more active by addition of cobalt or nickel. When promoted with cobalt sulfide (CoS), making what is called cobalt-molybdenum catalysts, it is widely used in hydrodesulfurization (HDS) processes. The nickel sulfide (NiS)-promoted version is used for hydrodenitrogenation (HDN) as well as hydrodesulfurization (HDS). The closely related tungsten compound (WS_2) is used in commercial hydrocracking catalysts. Other sulfides (iron sulfide, FeS , chromium sulfide, Cr_2S_3 , and vanadium sulfide, V_2S_5) are also effective and used in some catalysts. A valuable alternative to the base metal sulfides is palladium sulfide (PdS). Although it is expensive, palladium sulfide forms the basis for several highly active catalysts.

Catalyst poisoning can be minimized by mild hydrogenation to remove nitrogen, oxygen, and sulfur from feedstocks in the presence of more resistant catalysts, such as cobalt-molybdenum-alumina ($\text{Co-Mo-Al}_2\text{O}_3$). The reactions involved in nitrogen removal are somewhat analogous to those of the sulfur compounds and follow a stepwise mechanism to produce ammonia and the relevant substituted aromatic compound.

One of the chief problems with hydroprocessing residua is the deposition of metals, in particular vanadium, on the catalyst. It is not possible to remove vanadium from the catalyst, which must therefore be replaced when deactivated, and the time taken for catalyst replacement can significantly reduce the unit time efficiency. Fixed-bed catalysts tend to plug owing to solids in the feed or carbon deposits when processing residual feeds.

Hydrotreating Processes

Hydrotreating technology is one of the most commonly used refinery processes, designed to remove contaminants such as sulfur, nitrogen, condensed ring aromatics, or metals. The feedstocks used in the process range from naphtha to vacuum resid, and the products in most applications are used as environmentally acceptable clean fuels. Hydrotreating technology has a long history of commercial application since 1950s, with more than 500 licensed units placed in operation worldwide. Furthermore, recent regulatory requirements to produce ultra-low-sulfur diesel (ULSD) and gasoline have created a very dynamic market as refiners must build new or revamp their existing assets to produce the low-sulfur, even no-sulfur fuels.

Hydrotreating is carried out by charging the feed to the reactor, together with a portion of all the hydrogen produced in the catalytic reformer. Suitable catalysts are tungsten-nickel sulfide, cobalt-molybdenum-alumina, nickel oxide-silica-alumina, and platinum-alumina. Most processes employ cobalt-molybdenum catalysts, which generally contain approximately 10% by weight molybdenum oxide and less than 1% by weight cobalt oxide supported on alumina. The temperatures employed are in the range of 300 to 345°C (570 to 850°F), and the hydrogen pressures are approximately 500 to 1,000 psi.

For distillate feedstocks, the reaction generally takes place in the vapor phase but, depending on the application, may be a mixed-phase reaction. The reaction products are cooled in a heat exchanger and led to a high-pressure separator where hydrogen gas is separated for recycling. Liquid products from the high-pressure separator flow to a low-pressure separator (stabilizer) where dissolved gases are removed. The product may then be fed to a reforming or cracking unit if desired. As a note, the crude oil refining industry often employs two-stage processes in which the feedstock undergoes both hydrotreating and hydrocracking (Figure H-2).

Figure H-2 Two-stage hydrotreating.

In the first, or pretreating, stage, the main purpose is conversion of nitrogen compounds in the feed to hydrocarbon derivatives and to ammonia by hydrogenation and mild hydrocracking. Typical conditions are 340 to 930°C (650 to 1,740°F), 150 to 2,500 psi (1 to 17 MPa), and a catalyst contact time of 0.5 to 1.5 h; up to 1.5% w/w hydrogen is absorbed, partly by conversion of the nitrogen compounds but chiefly by aromatic compounds that are hydrogenated. It is most important to reduce the nitrogen content of the product oil to less than 0.001% w/w (10 parts per million). This stage is usually carried out with a bifunctional catalyst containing hydrogenation promoters, for example, nickel and tungsten or molybdenum sulfides, on an acid support, such as silica-alumina.

The metal sulfides hydrogenate aromatics and nitrogen compounds and prevent deposition of carbonaceous deposits; the acid support accelerates nitrogen removal as ammonia by breaking carbon-nitrogen bonds. The catalyst is generally used as 1/8 x 1/8 inch (0.32 x 0.32 cm) or 1/16 X 1/8 inch (0.16 x 0.32 cm) pellets, formed by extrusion.

Most of the hydrotreating cracking is accomplished in the first stage. Ammonia and some gasoline are usually removed from the first-stage product, and then the remaining first-stage product, which is low in nitrogen compounds, is passed over the second-stage catalyst. Again, typical conditions are 300 to 370°C (600 to 700°F), 1,500 to 2,500 psi (10 to 17 MPa) hydrogen pressure, and 0.5 to 1.5 h contact time; 1 to 1.5% w/w hydrogen may be absorbed. Conversion to gasoline or jet fuel is seldom complete in one contact with the catalyst, so the lower-boiling constituents are removed by distillation of the products and the heavier, higher-boiling product combined with fresh feed and recycled over the catalyst until it is completely converted.

See also: Refining.

Hydrotreating – Process Parameters

All hydrotreating processes react hydrogen with a hydrocarbon feedstock to produce hydrogen sulfide and a hydrocarbon product free of heteroatoms and metals.

In the process, the feedstock is preheated and mixed with hot recycle gas containing hydrogen and the mixture is passed over the catalyst in the reactor section at temperatures between 290 to 450°C (550 to 850°F) and pressures between 150 and 3,000 psig (1 to 20.7 MPa gauge). The reactor effluent is then cooled by heat exchange, and desulfurized liquid hydrocarbon product and recycle gas are separated at essentially the same pressure as used in the reactor. The recycle gas is then scrubbed and/or purged of the hydrogen sulfide and low-boiling hydrocarbon gases, mixed with fresh hydrogen makeup, and preheated prior to mixing with hot hydrocarbon feedstock.

The recycle gas scheme is used in the hydrodesulfurization process to minimize physical losses of expensive hydrogen. Hydrodesulfurization reactions require a high hydrogen partial pressure in the gas phase to maintain high desulfurization reaction rates and to suppress carbon laydown (catalyst deactivation). The high hydrogen partial pressure is maintained by supplying hydrogen to the reactors at several times the chemical hydrogen consumption rate. The majority of the unreacted hydrogen is cooled to remove hydrocarbon derivatives, recovered in the separator, and recycled for further utilization. Hydrogen is physically lost in the process by solubility in the desulfurized liquid hydrocarbon product, and from losses during the scrubbing or purging of hydrogen sulfide and low-boiling hydrocarbon gases from the recycle gas.

The operating conditions in distillate hydrodesulfurization are dependent upon the feedstock as well as the desired degree of desulfurization or quality improvement. Kerosene and low-boiling gas oils are generally processed at mild severity and high throughput, whereas low-boiling catalytic cycle oils and thermal distillates require slightly more severe conditions. Higher-boiling distillates, such as vacuum gas oils and lube oil extracts, require the most severe conditions.

The principal variables affecting the required severity in distillate desulfurization are: (i) catalyst life, (ii) feedstock properties, (iii) hydrogen partial pressure, (iv) reaction temperature, and (v) space velocity.

Catalyst Life

Catalyst life depends on the charge stock properties and the degree of desulfurization desired. The only permanent poisons to the catalyst are metals in the feedstock that deposit on the catalyst, usually quantitatively, causing permanent deactivation as they accumulate. However, this is usually of little concern except when deasphalted oils are used as feedstocks since most distillate feedstocks contain low amounts of metals. Nitrogen compounds are a temporary poison to the catalyst, but there is essentially no effect on catalyst aging except that caused by a higher temperature requirement to achieve the desired desulfurization. Hydrogen sulfide can be a temporary poison in the reactor gas, and recycle gas scrubbing is employed to counteract this condition.

Providing that pressure drop buildup is avoided, cycles of 1 year or more and an ultimate catalyst life of three years or more can be expected. The catalyst employed can be regenerated by normal steam-air or recycle combustion gas-air procedures. The catalyst is restored to near fresh activity by regeneration during the early part of its ultimate life. However, permanent deactivation of the catalyst occurs slowly during usage and repeated regenerations, so replacement becomes necessary.

Feedstock Properties

The character of the feedstock properties, especially the feed boiling range, has a definite effect on the ultimate design of the desulfurization unit and process flow. In agreement, there is a definite relationship between the percent by weight sulfur in the feedstock and the hydrogen requirements.

In addition, the reaction rate constant in the kinetic relationships decreases rapidly with increasing average boiling point in the kerosene and low-boiling gas oil range but much more slowly in the high-boiling gas oil range. This is attributed to the difficulty in removing sulfur from ring structures present in the entire high-boiling gas oil boiling range.

The hydrodesulfurization of light (low-boiling) distillate (naphtha or kerosene) is one of the more common catalytic hydrodesulfurization processes since it is usually used as a pretreatment of such feedstocks prior to deep hydrodesulfurization or prior to catalytic reforming. This is similar to the concept of pretreating residua prior to hydrocracking to improve the quality of the products. Hydrodesulfurization of such feedstocks is required because sulfur compounds poison the precious-metal catalysts used in reforming and desulfurization can be achieved under relatively mild conditions and is near quantitative. If the feedstock arises from a cracking operation, hydrodesulfurization will be accompanied by some degree of saturation resulting in increased hydrogen consumption.

The hydrodesulfurization of low-boiling (naphtha) feedstocks is usually a gas-phase reaction and may employ the catalyst in fixed beds, and (with all of the reactants in the gaseous phase) only minimal diffusion problems are encountered within the catalyst pore system. It is, however, important that the feedstock be completely volatile before entering the reactor as there may be the possibility of pressure variations (leading to less satisfactory results) if some of the feedstock enters the reactor in the liquid phase and is vaporized within the reactor.

In applications of this type, the sulfur content of the feedstock may vary from 100 ppm to 1% and the necessary degree of desulfurization to be effected by the treatment may vary from as little as 50% to more than 99%. If the sulfur content of the feedstock is particularly low, it will be necessary to pre-sulfide the catalyst. For example, if the feedstock only has 100 to 200 ppm sulfur, several days may be required to sulfide the catalyst as an integral part of the desulfurization process even with complete reaction of all of the feedstock sulfur to, say, cobalt and molybdenum (catalyst) sulfides. In such a case, pre-sulfiding can be conveniently achieved by addition of sulfur compounds to the feedstock or by addition of hydrogen sulfide to the hydrogen.

Generally, hydrodesulfurization of naphtha feedstocks to produce catalytic reforming feedstocks is carried to the point where the desulfurized feedstock contains less than 20 ppm sulfur. The net hydrogen produced by the reforming operation may actually be sufficient to provide the hydrogen consumed in the desulfurization process.

The hydrodesulfurization of middle distillates is also an efficient process, and applications include predominantly the desulfurization of kerosene, diesel fuel, jet fuel, and heating oil that boil over the general range 250 to 400°C (480 to 750°F). However, with this type of feedstock, hydrogenation of the higher-boiling catalytic cracking feedstocks has become increasingly important where hydrodesulfurization is accomplished alongside the saturation of condensed-ring aromatic compounds as an aid to subsequent processing.

Under the relatively mild processing conditions used for the hydrodesulfurization of these particular feedstocks, it is difficult to achieve complete vaporization of the feed. Process conditions may dictate that only part of the feedstock is actually in the vapor phase and that sufficient liquid phase is maintained in the catalyst bed to carry the larger molecular constituents of the feedstock through the bed. If the amount of liquid phase is insufficient for this purpose, molecular stagnation (leading to carbon deposition on the catalyst) will occur.

Hydrodesulfurization of middle distillates causes a more marked change in the specific gravity of the feedstock, and the amount of low-boiling material is much more significant when compared with the naphtha-type feedstock. In addition, the somewhat more severe reaction conditions (leading to a designated degree of hydrocracking) also cause an overall increase in hydrogen consumption when middle distillates are employed as feedstocks in place of the naphtha.

High-boiling distillates, such as the atmospheric and vacuum gas oils, are not usually produced as a refinery product but merely serve as feedstocks to other processes for conversion to lower-boiling materials. For example, gas oils can be desulfurized to remove more than 80% of the sulfur originally in the gas oil with some conversion of the gas oil to lower-boiling materials. The treated gas oil (which has a reduced carbon residue as well as lower sulfur and nitrogen contents relative to the untreated material) can then be converted to lower-boiling products in, say, a catalytic cracker where an improved catalyst life and volumetric yield may be noted.

Hydrogen Partial Pressure

The important effect of hydrogen partial pressure is the minimization of coking reactions. If the hydrogen pressure is too low for the required duty at any position within the reaction system, premature aging of the remaining portion of catalyst will be encountered. In addition, the effect of hydrogen pressure on desulfurization varies with feed boiling range. For a given feed, there exists a threshold level above which hydrogen pressure is beneficial to the desired desulfurization reaction. Below this level, desulfurization drops off rapidly as hydrogen pressure is reduced.

Reaction Temperature

A higher reaction temperature increases the rate of desulfurization at constant feed rate, and the start-of-run temperature is set by the design desulfurization level, space velocity, and hydrogen partial pressure. The capability to increase temperature as the catalyst deactivates is built into the most process or unit designs. Temperatures of 415°C (780°F) and above result in excessive coking reactions and higher than normal catalyst aging rates. Therefore, units are designed to avoid the use of such temperatures for any significant part of the cycle life.

Space Velocity

As the space velocity is increased, desulfurization is decreased, but increasing the hydrogen partial pressure and/or the reactor temperature can offset the detrimental effect of increasing space velocity.

See also: Hydrocracking, Refining.

Hydrous Pyrolysis

Hydrous pyrolysis is the thermal decomposition which takes place when organic compounds are heated to high temperatures in the presence of water. For example, steam cracking is used in the petroleum industry to produce the lower-molecular-weight olefins. Steam cracking uses water in the gas phase, whereas many hydrous pyrolysis processes use superheated water in the liquid phase.

Hydrous pyrolysis could find use in biomass technology and may be a significant process in the creation of shale oil since water under pressure (at high temperature) causes more efficient breakdown of kerogen. Generation and expulsion a bio-oil from biomass shale by hydrous pyrolysis through use of the formation water may provide a means of producing a partially upgraded bio-oil. Minerals may also be anticipated to play a role in hydrous pyrolysis reactions either through a catalytic effect or direct involvement.

Hydroxylation

The earliest method for conversion of olefins into alcohols involved their absorption in sulfuric acid to form esters, followed by dilution and hydrolysis, generally with the aid of steam. In the case of ethyl alcohol, the direct catalytic hydration of ethylene can be employed. Ethylene is readily absorbed in 98 to 100% sulfuric acid at 75 to 80°C (165 to 175°F), and both ethyl and diethyl sulfate are formed; hydrolysis takes place readily on dilution with water and heating.

The direct hydration of ethylene to ethyl alcohol is practiced over phosphoric acid on diatomaceous earth or promoted tungsten oxide under 100 psi pressure and at 300°C (570°F):

Purer ethylene is required in direct hydration than in the acid absorption process, and the conversion per pass is low, but high yields are possible by recycling. Propylene and the normal butenes can also be hydrated directly.

Ethylene, produced from ethane by cracking, is oxidized in the presence of a silver catalyst to ethylene oxide:

The vast majority of the ethylene oxide produced is hydrolyzed at 100°C to ethylene glycol:

Approximately 70% of the ethylene glycol produced is used as automotive antifreeze, and much of the rest is used in the synthesis of polyesters.

Of the higher alkenes, one of the first alcohol syntheses practiced commercially was that of isopropyl alcohol from propylene. Sulfuric acid absorbs propylene more readily than it does ethylene, but care must be taken to avoid polymer formation by keeping the mixture relatively cool and using acid of approximately 85% strength at 300 to 400 psi pressure; dilution with inert oil may also be necessary. Acetone is readily made from isopropyl alcohol, either by catalytic oxidation or by dehydrogenation over metal (usually copper) catalysts.

Secondary butyl alcohol is formed on absorption of 1-butene or 2-butene by 78 to 80% sulfuric acid, followed by dilution and hydrolysis. Secondary butyl alcohol is converted into methyl ethyl ketone by catalytic oxidation or dehydrogenation.

There are several methods for preparing higher-molecular-weight alcohol derivatives. One method in particular the so-called Oxo reaction and involves the direct addition of carbon monoxide (CO) and a hydrogen (H)

atom across the double bond of an olefin to form an aldehyde (RCH=O), which in turn is reduced to the alcohol (RCH_2OH). Hydroformylation (the Oxo reaction) is accomplished by contacting the olefin with synthesis gas (1:1 carbon monoxide-hydrogen) at 75 to 200°C (165 to 390°F) and 1,500 to 4,500 psi over a metal catalyst, usually cobalt. The active catalyst is held to be cobalt hydrocarbonyl $\text{HCO}(\text{CO})_4$, formed by the action of the hydrogen on dicobalt octacarbonyl.

A wide variety of olefins enter the reaction, those containing terminal unsaturated being the most active. The hydroformylation is not specific; the hydrogen and carbon monoxide add across each side of the double bond. Thus propylene gives a mixture of 60% n-butyraldehyde and 40% iso-butyraldehyde. Terminal (RCH=CH_2) and non-terminal ($\text{RCH=CHR}'$) olefins, such as 1-pentene and 2-pentene, give essentially the same distribution of straight-chain and branched-chain C_6 aldehydes, indicating that rapid isomerization takes place. Simple branched structures add mainly at the terminal carbon; iso-butylene forms 95% iso-valeraldehyde and 5% trimethyl acetaldehyde.

Commercial application of the synthesis has been most successful in the manufacture of iso-octyl alcohol from a refinery C_3 - C_4 copolymer, decyl alcohol from propylene trimer, and tridecyl alcohol from propylene tetramer. Important outlets for the higher alcohols lie in their sulfonation to make detergents and the formation of esters with dibasic acids for use as plasticizers and synthetic lubricants.

The hydrolysis of ethylene chlorohydrin ($\text{HOCH}_2\text{CH}_2\text{Cl}$) or the cyclic ethylene oxide produces ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$). The main use for this chemical is for antifreeze mixtures in automobile radiators and for cooling aviation engines; considerable amounts are used as ethylene glycol dinitrate in low-freezing dynamite. Propylene glycol is also made by the hydrolysis of its chlorohydrin or oxide.

Glycerin can be derived from propylene by high-temperature chlorination to produce alkyl chloride, followed by hydrolysis to allyl alcohol and then conversion with aqueous chloride to glycerol chlorohydrin, a product that can be easily hydrolyzed to glycerol (glycerin).

Glycerin has found many uses over the years; important among these are as solvent, emollient, sweetener, in cosmetics, and as a precursor to nitroglycerin and other explosives.

Hygas Gasifier

The Hygas gasifier, developed by the Institute of Gas Technology, was originally designed to receive a relatively pure hydrogen stream produced in a separate unit.

Three systems were considered: (i) a steam-oxygen gasification system, as in the Hydrane process, (ii) an electrothermal gasification system in which the heat for steam gasification is provided electrically, thus reducing the amount of carbon dioxide to be removed, and (iii) a steam/iron process. The steam/oxygen process has been the method of choice.

The carbon oxides cannot be removed from the steam/oxygen-gasification off gas in the integrated reactor, so the Hygas system is no longer a true hydrogasification process.

The high methane concentrations obtained in the Hydrane process cannot be realized in the integrated Hygas unit due to the lower hydrogen concentrations prevailing. As with the Hydrane system, the Hygas unit has a first dilute-phase stage followed by a second dense-phase fluidized bed stage.

See also: Gasification, Gasification of Biomass, Hydrogasification, Hydrane Gasifier.

Hypro Process

The Hypro process is a continuous catalytic method for hydrogen manufacture from natural gas or from refinery effluent gases. The process is designed to convert natural gas:

Hydrogen is recovered by phase separation to yield hydrogen of approximately 93% purity; the principal contaminant is methane.

See also: Hydrogen Production.

Ideal Gas

An ideal gas is a gas in which all collisions between atoms or molecules are perfectly elastic and in which there are no intermolecular attractive forces. An ideal gas can be characterized by three variables which are (i) the absolute pressure, P , (ii) the volume, V , and (iii) the absolute temperature, T . The relationship between these variables is called the *ideal gas law*:

$$PV = nRT = NkT$$

In this equation, n is the number of moles, R is the universal gas constant (8.3145 J/mol K), N is the number of molecules, and k is the Boltzmann constant (1.38066×10^{-23}). Thus: $J/K = 8.617385 \times 10^{-5} \text{ eV/K}$ and $k = R/N_A$, where N_A is the Avogadro number ($6.0221 \times 10^{23} / \text{mol}$).

The ideal gas law can arise from the pressure of gas molecules colliding with the walls of a container. And one mole of an ideal gas at standard temperature and pressure occupies 22.4 liters. However, natural gas is a non-ideal gas and does not obey the ideal gas law but obeys the modified gas law:

$$PV = nZRT$$

P is the pressure, V is the volume, T is the absolute temperature (degree Kelvin), Z is the compressibility, n is the number of kilo-moles of the gas, and R is the gas constant.

For example, if all other factors remained constant, when the volume of a certain mass of gas is reduced by 50%, the pressure would double, and so on. As a gas, it would expand to fill any volume it is in. However the compressibility, Z , is the factor which differentiates natural gas from an ideal gas. For methane, Z is 1 at 1 bar but decreases to 0.85 at 100 atmospheres, both at 25°C , that is, it compresses to a smaller volume than the proportional relationship.

Ideal Gas Law

An ideal gas is a gas in which all collisions between atoms or molecules are perfectly elastic and in which there are no intermolecular attractive forces. An ideal gas can be characterized by three variables: (i) absolute pressure, P , (ii) volume, V , and (iii) absolute temperature, T . The relationship between them is called the *ideal gas law*:

$$PV = nRT = NkT$$

n = number of moles, R = universal gas constant ($= 8.3145 \text{ J/mol K}$), N = number of molecules, k = Boltzmann constant ($= 1.38066 \times 10^{-23} \text{ J/K} = 8.617385 \times 10^{-5} \text{ eV/K}$), $k = R/N_A$, N_A = the Avogadro number $= 6.0221 \times 10^{23} / \text{mol}$.

The ideal gas law can arise from the pressure of gas molecules colliding with the walls of a container. And one mole of an ideal gas at standard temperature and pressure occupies 22.4 liters. However, natural gas is a non-ideal gas and does not obey the ideal gas law but obeys the modified gas law:

$$PV = nZRT$$

P is the pressure, V is the volume, T is the absolute temperature (degree Kelvin), Z is the compressibility, n is the number of kilo-moles of the gas, and R is the gas constant.

For example, if all other factors remained constant, when the volume of a certain mass of gas is reduced by 50%, the pressure would double and so on. As a gas, it would expand to fill any volume it is in. However the compressibility, Z , is the factor which differentiates natural gas from an ideal gas. For methane, Z is 1 at 1 bar but decreases to 0.85 at 100 atmospheres, both at 25°C, that is, it compresses to a smaller volume than the proportional relationship.

The gas deviation factor, z , is close to 1 at low pressures and high temperatures which means the gas behaves as an ideal gas at these conditions. At standard or atmospheric conditions, the gas z factor is always approximately 1. As the pressure increases, the z factor first decreases to a minimum, which is approximately 0.27 for the critical temperature and critical pressure. For temperatures of 1.5 times the critical temperature, the minimum z factor is approximately 0.77 and for temperatures of twice the critical temperature, the minimum z factor is 0.937. At high pressures, the z factor increases above 1 where the gas is no longer super-compressible. At these conditions, the specific volume of the gas is becoming so small and the distance between molecules is much smaller, so that the density is affected by the volume occupied by the individual molecules. Hence, the z factor continues to increase above unity as the pressure increases.

The gas deviation factor, z , is commonly determined by measuring the volume of a sample of the natural gas at a specific pressure and temperature, and then measuring the volume of the same quantity of gas at atmospheric pressure and at a temperature sufficiently high so that the hydrocarbon mixture is in the vapor phase. If the gas deviation factor is not measured, it may be estimated from its specific gravity. The method uses a correlation to estimate pseudo-critical temperature and pseudo-critical pressure values from the specific gravity.

IFPEXOL Process

The IFPEXOL process is a methanol-based process which has the simultaneous capability to dehydrate a gas stream, to remove acid gas from a gas stream, and to control hydrocarbon dew point. More specifically, the IFPEXOL-1 is used for water removal and hydrocarbon dew point control while the IFPEXOL-2 process is used predominantly for acid gas removal.

The novel concept behind the IFPEXOL-1 process is to use a portion of the water-saturated inlet feed to recover the methanol from the aqueous portion of the low temperature separator. That approach has solved a major problem with methanol injection in large facilities, the methanol recovery via distillation. Beyond that simple discovery, the cold section of the process is remarkably similar to a basic methanol injection process. Modifications to the process include water washing the hydrocarbon liquid from the low temperature separator to enhance the methanol recovery.

The IFPEXOL-2 process for acid gas removal is similar to an amine-type process except for the operating temperatures. The absorber operates below -29°C (-20°F) to minimize methanol losses, and the regenerator operates at approximately 90 psi. Cooling is required on the regenerator condenser to recover the methanol. This process usually follows the IFPEXOL-1 process, so excessive hydrocarbon absorption is not as great a problem.

Methanol is probably one of the most versatile solvents for processing gas streams. Historically, methanol was the first commercial organic physical solvent and has been used for hydrate inhibition, gas dehydration, gas sweetening, and liquids recovery. Most of these applications involve low temperature where the physical properties of methanol are advantageous when compared to other solvents which exhibit high viscosity problems or even solids formation. Operation at low temperatures tends to suppress methanol's most significant disadvantage, high solvent loss. Methanol shows both polar and non-polar characteristics, and these characteristics give methanol the unique ability to be used in an extensive range of applications.

IFP Spent Tire Depolymerization Process

A relatively new approach to the decomposition of used tires is the IFP process developed by the French Institute of Petroleum. Unlike the other tire pyrolysis processes, the IFP process is different in that it is a batch process that does not require pretreatment of the scrap tire.

In the process, whole tires are placed in a basket and lowered into the reactor where hot oil at 380°C (715°F) is sprinkled on to the surface of the tire. A chemical reaction between the hot oil and tires causes the depolymerization of the rubber.

After the tires have been completely depolymerized, the reactor is cooled to 100°C (212°F). The off-gases are sent to a distillation column. The column separates the gas and low-boiling hydrocarbon fractions. The resultant gas is sent for further purification into a C₄-C₆ fraction and gasoline constituents (C₈-C₁₀), and the low-boiling hydrocarbon derivatives are recycled to the reactor. The recycled hydrocarbon fraction is used to dilute the viscous fuel oil generated during the depolymerization process. Upon evacuating the reactor, the scrap metal is removed and sent off-site for salvage.

Since the process is operated in a batch mode, the concern over having enough tires for continuous feed is eliminated.

Ignifluid Combustion System

In the Ignifluid system, an air-blown fluidized bed of coarse particles of the fuel generates a low heat content fuel gas, which is burned in secondary combustion within the free space above the fluidized bed.

Combustion of carbonaceous feedstocks in a high-temperature fluidized bed with clinker formation was developed as the Ignifluid boiler. In fluidized-bed combustion, the fuel is dispersed and burnt in a fluidized bed of inert particles. The amount of fuel that can be burnt in a fluidized bed is determined by the air-supply rate. In fluidized combustion, the fuel is burnt within a fluidized bed of mineral matter coal ash, silica sand, or limestone for sulfur retention. The passage of the air for combustion through the bed maintains the particles in a violently fluidized state. Interest in combustion of oil in fluidized beds is a result of their capability of burning the entire range of fuel oils from gas oil to vacuum residues and of reducing the emission of sulfur dioxide by addition of limestone. Boilers for industrial steam raising or heating, of either the water tube or shell type, can be fired by fluidized combustion.

The Ignifluid fuel-burning system consists of an inclined chain-grate stoker with combustion air supplied at high velocity (approximately 50 feet/second) through the stoker bars at which the crushed carbonaceous feedstock, at the upper end of the chain-grate stoker, is blown off the grates and burns in suspension. The larger feedstock particles recirculate in the space above the grates until burning is complete. Ash is agglomerated into spheres approximately 1.0 inch in diameter, some of which may remain in the space between the furnace walls and the chain grate to provide a sloping sidewall to redirect recirculating particles of feedstock into the combustion zone. The ash is eventually conveyed, by the moving stoker gates, to an ash pit.

Ignitability

Ignitability is a property that is characteristic of liquids whose vapors are likely to ignite in the presence of ignition source; also characteristic of non-liquids that may catch fire from friction or contact with water and that burn vigorously. Also, here are three types of ignitable forms: (i) liquids with a flash point—the lowest temperature at which fumes above waste ignite of 60°C (140°F) which include alcohol, gasoline, and acetone, (ii) solids that spontaneously combust, and (iii) oxidizers and compressed gasses.

The ignitability properties of exposed material depends on: (i) the heat supplied, (ii) the exposure time, (iii) the presence or absence of flames, (iv) the rate of heat release, (v) the rate of flame spread, and (vi) the gas temperature.

See also: Hazardous Waste.

Ignitable Liquid

An ignitable liquid is a liquid that has a flash point of less than 60°C (140°F). Examples are benzene, hexane, heptane, benzene, pentane, petroleum ether (low boiling), toluene, and xylene(s). An aqueous solution that has a pH of less than or equal to 2, or greater than or equal to 12.5 is considered *corrosive*.

Corrosive materials also include substances such as sodium hydroxide and some other acids or bases. Chemicals that react violently with air or water are considered reactive. Examples are sodium metal, potassium metal, phosphorus, etc. Reactive materials also include strong oxidizers such as perchloric acid (HClO_4), and chemicals capable of detonation when subjected to an initiating source, such as solid, dry ($<10\% \text{H}_2\text{O}$) picric acid, benzoyl peroxide, or sodium borohydride (NaBH_4). Solutions of certain cyanide or sulfides that could generate toxic gases are also classified as reactive.

Immiscibility

Immiscibility is the formation of separate phases, the formation of carbonaceous solids, the separation of waxy materials, the separation of asphaltene constituents, an increase in viscosity of the material during storage, and the precipitation of oxidized or polymerized products. Immiscibility occurs when two or more fluids that do not have complete mutual solubility and co-exist as separate phases.

Residual fuel oils are produced by the blending of residual products with a diluent such as middle distillate to produce the grade of fuel oil required. This provides untold pathways, both chemical and physical, for problems such as immiscibility when these streams are mixed. For example, when vacuum residua serve as fuel oil stock rather than as a feedstock for visbreaking, it must be blended with other feed streams; immiscibility can and often does occur, especially if a blending stock does not contain sufficient aromatic content to solubilize the high asphaltene content of the vacuum residue.

See also: Immiscibility – Test Methods, Incompatibility.

Immiscibility – Test Methods

There are several test protocols that give a degree of the potential incompatibility tendencies of a fuel. The compatibility spot test (ASTM D4740) is one of these procedures. In brief, a drop of preheated fuel is thermally stressed at 100°C (212°F) for one hour and the spot examined for solids formation. Fuel blends are treated the same, each fuel separately and then the blend.

A second procedure (ASTM D2781) gives a compatibility rating based on how far a fuel and the blend spread on a specific brand of chromatographic paper. The rating scale is based on whether the spot gives a homogeneous (in terms of color) spot or a heterogeneous spot of light and dark areas.

A third procedure is known as the xylene equivalent test and is also a spot test on chromatographic paper. It differs from the other spot tests in that it used the percentage of xylene and iso-octane solvent that is required to be added to the fuel blend to give a homogeneous spot. Finally, a hot filtration test is used for an estimate of the potential for sludge formation.

See also: Immiscibility.

Impulse Turbines

Impulse turbines or turbine stages are simple, single-rotor or multirotor (compounded) turbines to which impulse blades are attached. Impulse blades can be recognized by their shape. Because they are usually used in the entrance high-pressure stages of a steam turbine, when the specific volume of steam is low and requires much smaller flow areas than at lower pressures, the impulse blades are short and have constant cross sections. Impulse turbines are also characterized by the fact that most or all of the enthalpy and hence the pressure drop occurs in the nozzles (or fixed blades that act as nozzles) and little or none in the moving blades. In the impulse turbine, no pressure drop (except that caused by friction) occurs in the moving blades.

A reaction turbine is a turbine that is constructed of rows of fixed and rows of moving blades, and the blades act as nozzles. The moving blades move as a result of the impulse of steam received (caused by change in momentum) and also as a result of expansion and acceleration of the steam relative to them, and they also act as nozzles. The enthalpy

drop per stage of one row fixed and one row moving blades is divided among them, often equally. Thus a blade with a 50% degree of reaction, or a 50% reaction stage, is one in which half the enthalpy drop of the stage occurs in the fixed blades and half in the moving blades. The pressure drops will not be equal, however. They are greater for the fixed blades and greater for the high pressure.

The single-stage impulse turbine (also called the de Laval turbine) consists of a single rotor to which impulse blades are attached. The steam is fed through one or several convergent-divergent nozzles which do not extend completely around the circumference of the rotor, so that only part the blades are impinged upon by the steam at any one time.

The velocity-compounded turbine was first proposed to solve the problems of a single-stage impulse turbine for use with high pressure and high temperature steam. The Curtis stage turbine, as it came to be called, is composed of one stage of nozzles as the single-stage turbine, followed by two rows of moving blades instead of one. These two rows are separated by one row of fixed blades attached to the turbine stator, which has the function of redirecting the steam leaving the first row of moving blades to the second row of moving blades.

Incinerator

An incinerator is a device used to burn solid or liquid residues or wastes as a method of disposal.

The incinerator is, simply, a furnace for burning refuse, and modern incinerators include pollution mitigation equipment such as flue-gas cleaning. There are various types of incinerator plant design which include (i) simple incinerator, (ii) fixed or moving grate incinerator, (iii) rotary-kiln incinerator, and (iv) the fluidized bed incinerator.

The simple incinerator is an older and simpler kind of incinerator that is, essentially, a brick-lined cell with a metal grate over a lower ash pit, with one opening in the top or side for loading and another opening in the side for removing incombustible solids clinker. Many small incinerators formerly found in apartment houses have now been replaced by waste compactors.

The fixed or moving grate incinerator is a large, fixed hearth incinerator with a moving grate. The moving grate enables the movement of waste through the combustion chamber to be optimized to allow a more efficient and complete combustion. These incinerators are typically used for combustion of municipal waste, and are thus referred to as MSWIs (municipal solid waste incinerators).

In the fixed or moving grate incinerator, the waste is introduced by a waste crane through the “throat” at one end of the grate, from where it moves down over the descending grate to the ash pit in the other end. Here, the ash is removed through a water lock. Part of the combustion air (primary combustion air) is supplied through the grate from below. This air flow also has the purpose of cooling the grate itself. Cooling is important for the mechanical strength of the grate, and many moving grates are also water cooled internally. Secondary combustion air is supplied into the boiler at high speed through nozzles over the grate. It facilitates complete combustion of the flue gases by introducing turbulence for better mixing and by ensuring a surplus of oxygen.

The incinerator must be designed to ensure that the flue gas reaches a temperature of at least 850°C (1,560°F) in order to ensure proper breakdown of organic toxins. This includes backup auxiliary burners (often fueled by oil), which are fired into the boiler in case the heating value of the waste becomes too low to reach this temperature alone. The flue gases are then cooled by heat transfer and heat the steam to typically 400°C (750°F) at a pressure of 550 to 600 psi for the electricity generation in the turbine. At this point, the flue gas has a temperature of around 200°C, and is passed to the flue gas cleaning system.

The rotary kiln incinerator has a primary chamber and secondary chamber. The primary chamber consists of an inclined refractory lined cylindrical tube. Movement of the cylinder on its axis facilitates movement of waste. In the primary chamber, there is conversion of solid fraction to gases, through volatilization, destructive distillation and partial combustion reactions. The secondary chamber is necessary to complete gas phase combustion reactions.

The clinker spills out at the end of the cylinder. A tall flue gas stack, fan, or steam jet supplies the needed draft. Ash drops through the grate, but many particles are carried along with the hot gases. The particles and any combustible gases may be combusted in an afterburner. To control air pollution, the combustion product gases are further treated with acid gas scrubbers to remove sulfuric acid and nitric acid emissions, and then routed through bag houses to remove particulate matter before the gases are released into the atmosphere.

The fluidized bed incinerator uses a strong airflow through a sand bed until a point is reached where the sand particles separate to let the air through and mixing and churning occurs, thus a fluidized bed is created and fuel and waste can now be introduced. The sand with the pre-treated waste and/or fuel is kept suspended on pumped air currents and takes on a fluid-like character. The bed is thereby thoroughly mixed and agitated keeping small inert particles and air in a fluid-like state. This allows all of the mass of waste, fuel, and sand to be fully circulated through the furnace.

The heat produced by an incinerator can be used to generate steam which may then be used to drive a turbine in order to produce electricity. However, the amount of energy produced is very much dependent upon the type and composition of the waste used as the feedstock. Much of the current thinking involves co-incineration of a specified amount of the waste (calculated on the basis of the carbon content of the waste) with, for example, coal to produce a consistent amount of energy.

Incineration has a number of outputs such as the ash and the emission to the atmosphere of flue gas. Before the flue gas cleaning, the flue gases may contain significant amounts of particulate matter, heavy metals, dioxins, furans, sulfur dioxide, hydrochloric acid, and polynuclear aromatic hydrocarbon derivatives (carcinogens).

The most publicized concerns related to the incineration of municipal solid wastes involve the fear that it produces significant amounts of dioxin and furan emissions. Dioxins and furans are considered by many to be serious health hazards. Older-generation incinerators that were not equipped with modern gas cleaning technologies were indeed significant sources of dioxin emissions. However, modern incinerators (due to advances in emission control designs and stringent regulations) must limit and even mitigate such emissions.

Particulate matter is collected by particle filtration, most often electrostatic precipitators and/or baghouse filters. Hydrogen chloride and sulfur dioxide are removed in scrubbers or as dry desulfurization by injection limestone slurry into the flue gas before the particle filtration. Wastewater from scrubbers must subsequently pass through a wastewater treatment plant. Nitrogen oxide (NO_x) emissions are either reduced by catalytic reduction with ammonia in a catalytic converter (selective catalytic reduction) or by a high temperature reaction with ammonia in the furnace (selective non-catalytic reduction). Heavy metals are often adsorbed on injected active carbon powder, which is collected by the particle filtration.

Incineration produces fly ash and bottom ash just as is the case when coal is combusted. The total amount of ash produced by municipal solid waste incineration ranges from 15 to 20% by weight of the waste, and the fly ash amounts to 0 to 10% of the total ash. The fly ash, by far, constitutes more of a potential health hazard than does the bottom ash because the fly ash often contains high concentrations of heavy metals such as lead, cadmium, copper, and zinc as well as small amounts of dioxins and furans. The bottom ash seldom contains significant levels of heavy metals.

While fly ash is always regarded as hazardous waste, bottom ash is generally considered safe for regular landfill after a certain level of testing defined by the local legislation. Ash, which is considered hazardous, may generally only be disposed of in landfills which are carefully designed to prevent pollutants in the ash from leaching into underground aquifers – or after chemical treatment to reduce its leaching characteristics.

See also: Combustion.

Inclined Grate Furnace

The inclined grate furnace (moving grate furnace, step grate furnace) is a type of furnace in which fuel enters at the top part of a grate in a continuous ribbon, passes over the upper drying section where moisture is removed, and descends into the lower burning section. Ash falls off the lower end of the grate, and is readily removed mechanically. This type of furnace is extremely versatile (in terms of flexibility of the ability to tolerate different types of fuel).

In the system, biomass fuel (for example wood) is delivered to the top of a sloping grate by auger (Figure 1) or by a ram-stoker and lock-hopper. This grate is constructed of several panels of firebars. Electric or hydraulic actuation moves these bars in sequence to encourage fuel to travel down the grate.

Primary air is supplied under the grate, and the fuel passes through a clear sequence of drying, volatile emission, and char burnout as it moves down the grate. This sequenced combustion is one of the great strengths of the design: by tuning the grate speed, fuel feed, and air supply, it is possible to burn a wide range of fuels. The addition of a

ceramic arch over the grate reflects heat back, encouraging drying and subsequent ignition, and thus permitting the combustion of wet fuels: up to 70% moisture has been achieved.

The furnace has a wide tolerance of fuel type, moisture, and particle size, and the positive movement of fuel down grate avoids clinkering and blockages. The furnace also has a high efficiency.

On the other hand, a relatively large fuel inventory can lead to slow response to load swings, although modulating controls using a lambda sensor and air trim improve this controllability. The furnace is often more expensive than other types of furnace.

See also: Biomass, Combustion.

Incompatibility

Incompatibility is the immiscibility of crude oil products and also of different crude oils which is often reflected in the formation of a separate phase after mixing and/or storage.

The incompatibility of liquid fuels has become a major issue over the past two decades as a result of the production of fuels from sources other than crude oil. Differences in fuel composition and in the chemical nature of the fuel constituents have all served to emphasize the issue of fuel incompatibility.

Briefly, incompatibility refers to the formation of a precipitate (or sediment) or phase separation when two liquids are mixed. The term instability is often used in reference to the formation of color, sediment, or gum in the liquid over a period of time. This term may be used in contrast to the formation of a precipitate in the near, almost immediate term. However, the terms are often used interchangeably. Gum formation alludes to the formation of soluble organic (usually considered to be polymeric) material, whereas sediment is considered to be insoluble organic (usually polymeric) material.

In general, fuel instability and incompatibility can be related to the existence of heteroatoms (i.e., containing nitrogen, oxygen, and sulfur). The degree of unsaturation of the fuel (i.e., the level of olefinic species) also plays a role in determining instability/incompatibility. Also, recent investigations have implicated catalytic levels of various oxidized intermediates and acids as especially deleterious for middle distillate fuels.

Fuel incompatibility can have many meanings. The most obvious example of incompatibility (immiscibility) is the inability of a hydrocarbon fuel and water to mix. In the present context, incompatibility usually refers to the presence of various polar functionalities (i.e., heteroatom function groups containing nitrogen, oxygen, or sulfur, and even various combinations of the heteroatoms) in the crude oil. As is often the case, some of the polar functional groups can survive the refining operations (perhaps with some change) and end up in the finished fuel products. Thereafter, the groups can participate in a variety of chemical reactions, leading to fuel deterioration and/or instability and incompatibility.

Fuel instability problems can be of two related types: high-temperature short-term reactions (oxidative instability) and ambient temperature long-term reactions (storage instability). Oxygen, nitrogen, and sulfur species can be implicated in both types of instability. The synergism between organic sulfur and nitrogen compounds with active oxygen species on the stability of middle distillate fuels is not well understood. Differences in fuel composition, reaction surface, quantity of dissolved oxygen, hydroperoxide concentration, and reaction temperature all contribute to the reported variations in fuel deterioration.

Both incompatibility and instability result in the formation and separation of degradation products or in other undesirable changes in the original properties of petroleum products. In the case of instability, there is a low resistance of the product to environmental influences during storage or to its susceptibility to oxidative or other degradation processes. In the case of incompatibility, degradation products form or changes occur due to an interaction of some chemical groups present in the components of the final blend.

To summarize, part of the problem of incompatibility arises from the manner in which the fuels react with oxygen during storage. The remainder of the problem may be due to the character of the individual constituents. Many of the constituents may be incompatible/immiscible with each other, thereby causing phase separation and hence, incompatibility. Another part of the problem (not to be underestimated) arises because of variations in terminology. The nonspecific application of various names is confusing and needs to be resolved.

See also: Immiscibility, Immiscibility – Test Methods, Instability and Incompatibility – Methods for Determining.

Indirect Liquefaction

Indirect liquefaction is the conversion of biomass to a liquid fuel through an intermediate step involving gasification of the feedstock to synthesis gas followed by the production of hydrocarbon liquids from the gas.

Thus, indirect liquefaction processes invoke the concept of a two-stage conversion operation in which the feedstock is first converted (by reaction with steam and oxygen) to produce a gaseous mixture that is composed primarily of carbon monoxide and hydrogen (synthesis gas; syn gas). The gas stream is subsequently purified (to remove sulfur, nitrogen, and any particulate matter) after which it is catalytically converted to a mixture of liquid hydrocarbon products.

The gasification step may be attained by means of any one of several processes. The exothermic nature of the process and the decrease in the total gas volume in going from reactants to products suggest the most suitable experimental conditions to use in order to maximize product yields. In practice, the Fischer-Tropsch reaction is carried out at temperatures on the order of 200 to 350°C (390 to 660°F) and at pressures up to 4,000 psi. The hydrogen/carbon monoxide ratio is usually at approximately 2.2:1 or 2.5:1. Since up to three volumes of hydrogen may be required to achieve the next stage of the liquids production, the synthesis gas must then be converted by means of the water-gas shift reaction) to the desired level of hydrogen:

After which the gaseous mix is purified (acid gas removal, etc.) and converted to a wide variety of hydrocarbon derivatives:

These reactions result primarily in low- and medium-boiling aliphatic compounds; present commercial objectives are focused on the conditions that result in the production of n-hydrocarbon derivatives as well as olefinic and oxygenated materials.

The efficiency of a two-stage process as compared with a single-stage liquefaction process (such as pyrolysis of biomass to bio-oil) is a disadvantage of the indirect liquefaction process, but the advantages of the indirect approach are (i) the gasification stage can tolerate a higher degree of impurities (such as mineral matter) in the feedstock, (ii) the feedstock to the liquefaction stage can be maintained at the desired hydrogen level irrespective of the nature and quality of the feedstock, (iii) a clean product is produced, and (iv) hydrogen from a variety of other hydrogen production methods may be employed thereby increasing the overall production of liquids from a given amount of biomass or waste.

See also: Synthesis Gas.

Indirect Liquefaction Processes

The indirect liquefaction of a carbonaceous feedstock involves a two-stage conversion operation in which the feedstock is first converted (by reaction with steam and oxygen) to produce a gaseous mixture that is composed primarily of carbon monoxide and hydrogen (syngas; synthesis gas). The gas stream is subsequently purified (to remove sulfur, nitrogen, and any particulate matter) after which it is catalytically converted to a mixture of liquid hydrocarbon products.

In addition to the production of fuel gas, the feedstock may be gasified to prepare synthesis gas (carbon monoxide, CO, and hydrogen, H₂), which may be used to produce a variety of products, including ammonia, methanol, and liquid hydrocarbon fuels.

The synthesis of hydrocarbon derivatives from carbon monoxide and hydrogen (synthesis gas) (the Fischer-Tropsch synthesis) is a procedure for the indirect liquefaction of coal. This process is the only coal liquefaction scheme currently in use on a relatively large commercial scale; South Africa is currently using the Fischer-Tropsch

process on a commercial scale in their SASOL complex, although Germany produced roughly 156 million barrels of synthetic crude oil annually using the Fischer-Tropsch process during the Second World War.

Thus, the indirect liquefaction of coal involves (as a first stage) the production of a synthesis gas mixture from the coal followed by the catalytic formation of hydrocarbon derivatives and oxygenated species from the synthesis gas. In the process, the feedstock is converted to gaseous products at temperatures in excess of 800°C (1,470°F), and at moderate pressures, to produce synthesis gas:

The gasification may be attained by means of any one of several processes, and the exothermic nature of the process and the decrease in the total gas volume in going from reactants to products suggest the most suitable experimental conditions to use in order to maximize product yields. The process should be favored by high pressure and relatively low reaction temperature. In practice, the Fischer-Tropsch reaction is carried out at room temperatures of 200 to 350°C (390 to 660°F) and at pressures of 75 to 4,000 psi; the hydrogen/carbon monoxide ratio is usually at approximately 2.2:1 or 2.5:1.

Since up to three volumes of hydrogen may be required to achieve the next stage of the liquids production, the synthesis gas must then be converted by means of the water-gas shift reaction) to the desired level of hydrogen:

After which the gaseous mix is purified (acid gas removal, etc.) and converted to a wide variety of hydrocarbon derivatives:

These reactions result primarily in low- and medium-boiling aliphatic compounds; present commercial objectives are focused on the conditions that result in the production of n-hydrocarbon derivatives as well as olefins and oxygenated materials.

Although the efficiency of a two-stage process as compared with a single-stage liquefaction process has often been cited as a disadvantage of the indirect liquefaction of coal, the advantages of the indirect approach are (i) the gasification stage can tolerate a higher degree of impurities (e.g., mineral matter) in the coal; (ii) the feed to the liquefaction stage can be maintained at the desired hydrogen level irrespective of the nature and quality of the feed coal; (iii) a clean product is produced; (iv) the method is adaptable to the use of the products from the underground gasification of coal; and (v) there is the added advantage that hydrogen from a variety of other hydrogen production methods may be employed thereby increasing the overall production of liquids from a given amount of coal.

Indirectly Heated Gasifiers

The fluidizing media for the biomass gasification are either air and steam or pure oxygen and steam. Air-blown or directly heated gasifiers use the exothermic reaction between the oxygen and organics to provide the heat necessary to devolatilize biomass and to convert residual carbon-rich chars. For directly heated gasifiers, the heat to drive the process is generated inside within the gasifier. When air is used, the product gas is diluted with nitrogen and typically has a dry basis calorific value of 110 to 160 Btu/ft³. The use of oxygen instead of air produces a medium heating value syngas, 265 to 400 Btu/ft³, suitable for combustion turbine application.

Oxygen production is expensive, and hence indirectly heated gasifiers which utilize the twin bed concept similar to fluid catalytic crackers (FCC) that are being used in refining crude oil are being developed for generation of medium calorific syngas using air as a fluidizing medium.

The syngas produced from the indirectly heated gasifiers are devoid of nitrogen contamination, and hence they are also favored for other gas-to-liquid-based technologies. The non-requirement of oxygen to generate medium heating value syngas, results in lower capital cost for the gasification plant.

If the gas turbines using fossil fuel (natural gas or diesel) which has heating value of approximately 885 Btu/ft³, need to be interchangeable with the biomass syngas, higher heating values are preferred. In a natural-gas-fired turbine, the gas is only approximately 2% of the flow and the rest is air for dilution and combustion, while in contrast, syngas accounts for 14 to 16% v/v of the total gas.

The IGCC (Integrated Gasification Combined Cycle) uses air as the gasifying agent and require modified turbine combustors to handle the low heating-value gas (110 to 190 Btu/ft³). The low calorific syngas up to 135 Btu/ft³ is only suitable for firing in the boiler or use in diesel engines.

The COGAS char gasifier (Figure 1) is an indirectly heated unit that has been developed for use in combination with a pyrolysis process to gasify the residual char remaining after pyrolysis.

The COGAS process typifies how a circulating heat transfer medium, in this case char, can be heated and then reintroduced into the gasifier to provide the required heat without diluting the product gas with nitrogen and without the need to produce pure oxygen.

In some indirectly heated systems, the heat transfer medium is selected to serve secondary functions that improve the overall gasifier performance. For example, in the CO₂ Acceptor process (Figure 2), lime (CaO) or dolomite (CaO-MgO) is used to chemically trap the hydrogen sulfide:

Much of the heat required is supplied by the highly exothermic reaction of the dolomite and carbon dioxide, rather than by the sensible heat of the heat transfer medium, as in the case of the COGAS gasifier. Removal of carbon dioxide and hydrogen sulfide from the synthesis gas directly in the gasifier has several important advantages.

The acceptor contains some 80 to 90% of the sulfur in the lignite, but only approximately 10% of this is driven off in the regenerator. The regenerator flue gas contains sulfur dioxide, and requires scrubbing before being released to the atmosphere.

Industrial Chemicals

Industrial chemicals are used widely in all kinds of industries. Although the use of these chemicals has played a major role in the development of industry and society in the past few decades, most current pollution problems are becoming more serious due to the ubiquitous industrial chemicals in the environment.

Industrial chemicals are released by volatilization, leakage, or leaching, either during the lifetime of a product or after ultimate disposal. Although not all of these constitute potential toxicity hazards, many will cause environmental pollution as a result of leakage during storage, from use in the environment or from their disposal—either directly, or of wastes containing them. Apart from industrial uses, a large number of chemicals are used in domestic products and so their use and disposal are less controlled than that of industrial chemicals. For example, industrial chemicals such as food additives, surfactants, and medicines are used directly in human life.

Although industrial chemicals play an important role in improving human health and standard of living, they have caused significant problems to the no-linger pristine environment. These anthropogenic contaminants include inorganic compounds, organic substances, heavy metals, and radionuclides. A health problem is posed whenever people become exposed to them, even at low concentrations.

Some industrial chemicals, particularly persistent organic pollutants, which occur in the environment are both highly toxic and difficult to remove. Moreover, industrial chemicals also include endocrine-disrupting chemicals that cause adverse health effects in an intact organism, or its progeny, as a result of changes in endocrine function. All of these compounds can cause adverse effects on human health and damage ecosystems. As

these chemicals in the environment cause great potential risk, great attention should be paid to recognizing them.

Organic chemicals are some of the important starting materials for a great number of major fuels industries and chemical industries. The production of organic chemicals as raw materials or reagents for other applications is a major sector of manufacturing polymers, pharmaceuticals, pesticides, paints, artificial fibers, food additives, etc. Organic synthesis on a large scale, compared to the laboratory scale, involves the use of energy, basic chemical ingredients from the petrochemical sector, catalysts, and after the end of the reaction, separation, purification, storage, packaging, distribution, etc. During these processes, there are many problems of health and safety for workers in addition to the environmental problems caused by their use and disposition as waste.

The industrial organic chemical industry uses feedstocks derived from natural gas and crude oil (approximately 90%), recovered coal tar condensates generated by coke production (approximately 10%) as well as from renewable sources such as the biomass industry.

The chemicals industry is diverse, comprising (i) basic or commodity chemicals, (ii) specialty chemicals derived from basic chemicals, such as adhesives and sealants, catalysts, coatings, electronic chemicals, and plastic additives, (iii) products derived from life sciences, such as pharmaceuticals, pesticides and products of modern biotechnology, and (iv) consumer care products, such as soap, detergents, bleaches, hair and skin care products, and fragrances.

The chemical industry involves the use of chemical processes such as chemical reactions and refining methods to produce a wide variety of solid, liquid, and gaseous materials. Most of these products serve to manufacture other items, although a smaller number go directly to consumers. Solvents, pesticides, lye, washing soda, and Portland cement provide a few examples of product used by consumers. The industry includes manufacturers of organic-industrial chemicals, petrochemicals, agrochemicals, polymers and rubber (elastomers), oleo-chemicals (oils, fats, and waxes), explosives, fragrances, and flavors.

Chemical processes such as chemical reactions operate in chemical plants to form new substances in various types of reaction vessels. In many cases, the reactions take place in special corrosion-resistant equipment at elevated temperatures and pressures with the use of catalysts. The products of these reactions are separated using a variety of techniques including distillation, especially fractional distillation, precipitation, crystallization, adsorption, filtration, sublimation, and drying.

The processes and product or products are usually tested during and after manufacture by dedicated instruments and on-site quality control laboratories to ensure safe operation and to assure that the product will meet required specifications. More organizations within the industry are implementing chemical compliance software to maintain quality products and manufacturing standards. The products are packaged and delivered by many methods, including pipelines, tank-cars, and tank-trucks (for both solids and liquids), cylinders, drums, bottles, and boxes. Chemical companies often have a research-and-development laboratory for developing and testing products and processes. These facilities may include pilot plants, and such research facilities may be located at a site separate from the production plant(s).

Industrial organic chemical manufacturers use and generate both large numbers and quantities of chemicals. The types of pollutants a single facility will release depend on the feedstocks, processes, equipment in use, and maintenance practices. These can vary over a short period of time (sometimes on an hour-to-hour basis) and can also vary with the part of the process that is underway. For example, for batch reactions in a closed vessel, the chemicals are more likely to be emitted at the beginning and end of a reaction step (associated with vessel loading and product transfer operations), than during the reaction.

Industrial organic synthesis followed a largely *stoichiometric* line of evolution that can be traced back to the synthesis of mauveine by Perkin, the subsequent development of the dyestuffs industry based on coal tar, and the fine chemicals and pharmaceuticals industries, which can be regarded as spin-offs from the dyestuffs industry. Consequently, fine chemicals and pharmaceuticals manufacture, which is largely the domain of synthetic organic chemists, is rampant with classical stoichiometric processes.

The desperate need for more catalytic methodologies in industrial organic synthesis is nowhere more apparent than in oxidation chemistry. For example, as any organic chemistry textbook will note that the reagent of choice for the oxidation of secondary alcohols to the corresponding ketones, a pivotal reaction in organic

synthesis, is the Jones reagent. The latter consists of chromium trioxide and sulfuric acid and is reminiscent of the phloroglucinol process referred to earlier. The introduction of the storage-stable pyridinium chlorochromate (PCC) and pyridinium dichromate (PDC) in the 1970s, represented a practical improvement, but the stoichiometric amounts of carcinogenic chromium(VI) remain a serious problem. Obviously, there is a definite need in the fine chemical and pharmaceutical industry for catalytic systems that are green and scalable and have broad utility.

Industrial Waste

Waste is the remains or by-product from a process for which no use is planned or foreseen. The words domestic (or municipal) and industrial are qualifiers of the source of the waste and, to some extent, also descriptive of the contents of the waste. Once a material has been designated as waste, it remains waste until it has been fully recovered and no longer poses a potential threat to the environment.

Industrial waste is a waste type produced by industrial operations, such as factories, mines, and refineries. Toxic waste and chemical waste are two more specific designations of industrial waste.

Industrial process wastes include a very wide range of materials, and the actual composition of industrial wastes in a country will depend on the nature of the industry. Wastes may occur as relatively pure substances or as complex mixtures of varying composition and in varying physicochemical states. Examples of the materials which may be found under this heading are general rubbish, organic wastes from food processing, acids, alkalis, metallic sludge, and tar. The most important feature of industrial wastes is that a significant proportion is regarded as hazardous or potentially toxic, thus requiring special handling, treatment, and disposal.

The energy content of waste can be harnessed directly by using the waste as a direct combustion fuel, or indirectly by processing them into another type of fuel. Recycling through thermal treatment ranges from using waste as a fuel source for cooking or heating, to fuel for boilers to generate steam and electricity in a turbine.

Pyrolysis and gasification are two related forms of thermal treatment where waste materials are heated to high temperatures with limited oxygen availability. The process usually occurs in a sealed vessel under high pressure.

Pyrolysis of solid waste converts the material into solid, liquid, and gas products. The liquid and gas can be burnt to produce energy or refined into other products. The solid residue (char) can be further refined into products such as activated carbon.

Gasification and advanced plasma arc gasification are used to convert organic materials directly into a synthetic gas (syngas) composed of carbon monoxide and hydrogen. The gas is then burnt to produce electricity and steam.

Inertial Separator

An inertial separator separates particulate matter or dust from gas streams using a combination of forces, such as centrifugal, gravitational, and inertial. These forces move the dust to an area where the forces exerted by the gas stream are minimal. The separated dust is moved by gravity into a hopper, where it is temporarily stored.

The three primary types of inertial separators are (i) settling chambers, (ii) baffle chambers, and (iii) centrifugal collectors. Neither settling chambers nor baffle chambers are commonly used in the minerals processing industry. However, their principles of operation are often incorporated into the design of more efficient dust collectors.

In gas processing, the gas passes through an inlet baffle to remove large liquid droplets, and then through a series of angled vanes that impart inertial forces on the smaller liquid droplets.

See also: Gas Cleaning.

Inferred Reserves

The term inferred reserves is also commonly used in addition to, or in place of, potential reserves (Table I-1).

Table I-1 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Inferred reserves are regarded as of a higher degree of accuracy than potential reserves, and the term is applied to those reserves that are estimated using an improved understanding of reservoir frameworks. The term also usually includes those reserves that can be recovered by further development of recovery technologies.

The differences between the data obtained from these various estimates can be considerable, but it must be remembered that any data related to the reserves of crude oil (and, for that matter, related to any other fuel or mineral resource) will always be open to questions related to the degree of certainty. Thus, in reality, and in spite of the use of self-righteous word-smithing, proven reserves may be a small part of the total hypothetical and/or speculative amounts of a resource.

Inherent Mineral Matter

Inherent mineral matter is the mineral matter which had its origin in the organic constituents of the plant but the extraneous mineral matter was brought into the plant by mechanical means from outside, for example, as dust by air or as suspended or dissolved material carried by water. The inherent mineral matter is also sometimes defined as the inorganic material combined with the organic coal substance, but such material need not be derived from the coal-forming plants.

Inherent mineral matter is usually much smaller in quantity than extraneous mineral matter and can be expected to differ quite markedly in composition from the inorganic residue of the major plant types. This is due to re-use (in no small part) of the inorganic elements by succeeding vegetation and to leaching of inorganic constituents by the waters percolating and flowing through the area during growth of the plants. The percolating waters may be presumed to have an increased dissolving action on the inorganic constituents because of their content of humic acids, carbon dioxide, and other products of decay. Furthermore, the differences in solubilities and reactions of the inorganic elements present in the plants dictate that these elements do not contribute to the mineral matter in proportion to their presence in the plant material.

Inorganic Chemicals

Inorganic chemistry is the branch of chemistry concerned with the properties and behavior of inorganic compounds. This field covers all chemical compounds except the myriad of carbon-based compounds (such as the hydrocarbon derivatives), which are the subjects of organic chemistry. The distinction between the two disciplines is far from absolute, and there is much overlap, most importantly in the sub-discipline of organometallic chemistry in which

organic compounds and metals from distinct and stable products. An example is tetraethyl lead which was formerly used in gasoline (until it was banned by various national environmental agencies) as an octane enhancer to prevent engine knocking or pinging during operation.

The term inorganic chemicals represents a broad class of substances encompassing all those chemicals that do not include carbon and its derivatives as their principal elements. The exceptions (alphabetically) are (i) carbide derivatives, which are compounds composed of carbon and less electronegative elements and are distinguished by the chemical bonding – ionic, covalent – which are generally prepared from metals or metal oxides at high temperatures (1,500°C, 2,730°F, or higher) by combining the metal with carbon, (ii) carbonate derivatives, which are salts of carbonic acid, H_2CO_3 , and characterized by the presence of the carbonate ion, a polyatomic ion with the formula of CO_3^{2-} , (iii) cyanate derivatives, which contain the cyanate anion ($\text{O}=\text{C}=\text{N}^-$), usually written OCN^- , – cyanate derivatives are also isomers of the much less stable fulminate anion $[\text{C}\equiv\text{N}^+\text{O}]^-$, and (iv) cyanide derivatives, which are chemical compounds that contain the group $\text{C}\equiv\text{N}$ that, in inorganic chemicals consists of a carbon atom triple-bonded to a nitrogen atom and is present as the anion CN^- leading to salts such as sodium cyanide (NaCN) and potassium cyanide (KCN) that are highly toxic.

In summary, many inorganic compounds are ionic compounds, consisting of cations and anions joined by ionic bonding. Examples of salts (which are ionic compounds) are magnesium chloride (MgCl_2) which consists of magnesium cations (Mg^{2+}) and chloride anions (Cl^-). In any salt, the proportions of the ions are such that the electric charges cancel out, so that the bulk compound is electrically neutral. Important classes of inorganic compounds are the oxides, the carbonates, the sulfates, and the halides. Many inorganic compounds are characterized by high melting points, ease of crystallization, and solubility – where some salts (such as sodium chloride, NaCl) are highly soluble in water; others (such as silica, silicon oxide, and SiO_2) are insoluble in water.

Inorganic Chemical Transformation Reactions

The various chemical transformation processes, which influence the presence and the analysis of inorganic chemicals at a particular site, although often represented by simple (and convenient) chemical equations, can be complex, and the true nature of the chemical transformation process is difficult to elucidate. The extent of transformation is dependent on many factors including (i) the properties of the chemical, (ii) the geology of the site, (iii) the climatic conditions, such as temperature, oxygen levels, and moisture, (iv) the type of micro-organisms present at the site, and (v) any other environmental conditions that can influence the life-cycle of the chemical. In fact, the primary factor controlling the extent of chemical transformation is the molecular composition of the inorganic chemicals contaminant.

Any chemical change can easily be represented with the help of chemical equations which is a simple representation of a chemical reaction and which involves the molecular or atomic formulas of reactants and products. On the basis of cleavage and formation of chemical bonds, most inorganic chemical reactions can be classified into four broad categories: (i) acid-base reactions, (ii) combination reactions, (iii) decomposition reactions, (iv) single displacement reactions, and (v) double displacement reactions.

One other type of reaction that occurs with inorganic chemicals and with organic chemicals is a coagulation reaction – for convenience, it is included here but is equally applicable to inorganic chemicals and to organic chemicals.

In the chemical sense, aggregation (especially particle agglomeration) refers to formation of assemblages in a suspension and represents a mechanism leading to destabilization of colloidal systems. During this process, particles dispersed in the liquid phase stick to each other, and spontaneously form irregular particle clusters, flocs, or aggregates. This phenomenon is also referred to as coagulation or flocculation, and such a suspension is also called unstable – both physically and chemically. Particle aggregation can be induced by adding salts or another chemical referred to as a coagulant or flocculant.

Particle aggregation is normally an irreversible process, and once particle aggregates have formed, they will not dissociate easily. In the course of aggregation, the aggregates will grow in size, and as a consequence, they may settle to the bottom of the container, which is referred to as sedimentation. Alternatively, a colloidal gel may form in concentrated suspensions which changes the rheological properties. The reverse process whereby particle aggregates

are disrupted and dispersed as individual particles, referred to as peptization, hardly occurs spontaneously, but may occur under stirring or shear. Colloidal particles may also remain dispersed in liquids for long periods of time (days to years). This phenomenon is referred to as colloidal stability, and such a suspension is said to be stable. In fact, stable suspensions are often obtained at low salt concentrations or by addition of chemicals referred to as stabilizers or stabilizing agents. Similar aggregation processes occur in other dispersed systems. For example, in an emulsion, they may also be coupled to droplet coalescence, and not only lead to sedimentation but also to creaming. In aerosols, airborne particles may equally aggregate and form larger clusters. In the chemical sense, creaming is the migration of the dispersed phase of an emulsion, under the influence of buoyancy. The particles float upwards or sink, depending on how large they are and how much less dense or more dense they may be than the continuous phase, and also how viscous or how thixotropic (a time-dependent shear thinning property) the continuous phase might be. For as long as the particles remain separated – the process is referred to as creaming.

Thus, a chemical transformation requires a chemical reaction to lead to the transformation of one chemical to another (Habashi, 1994). Typically, chemical reactions encompass changes that only involve the positions of electrons in the forming and breaking of chemical bonds between atoms, with no change to the nuclei (no change to the elements present), and can often be described by a relatively simple chemical equation; thus:

However, although the various chemical transformation processes that occur and which influence the presence and the analysis of inorganic chemicals at a particular site are often represented by simple (and convenient) chemical equations, the chemical transformation reactions can be much more complex than the equation indicates. In addition, a chemical reaction may proceed in the forward direction and processed to completion as well as in the reverse direction until the reactants and products reach an equilibrium state:

Thus,

Reactions that proceed in the forward direction to approach equilibrium are often described as spontaneous, requiring no input of free energy to go forward. On the other hand, non-spontaneous reactions require input of free energy to go forward (examples application of heat for the reaction to proceed). In inorganic chemical synthesis, different chemical reactions are used in combinations during the reaction in order to obtain a desired product. Also, in inorganic chemistry, a consecutive series of chemical reactions (where the product of a reaction is the reactant of the next reaction) are often encouraged to proceed by a variety of catalysts which increase the rates of biochemical reactions without themselves (the catalysts) being consumed in the reaction, so that syntheses and decompositions impossible under ordinary conditions can occur at the temperatures, pressures, and reactant concentrations present within a reactor and, by inference, in the current content within the environment.

This simplified equation does not truly illustrate the potential complexity of an inorganic chemical reaction, but such complexity must be anticipated when an inorganic chemical is transformed in an environmental ecosystem. Actual examples (listed alphabetically) of the reaction of inorganic chemicals in the environment are presented in the following subsections.

Inorganic Chemical Transformation Reactions – Hydrolysis Reactions

Hydrolysis is a double decomposition reaction with water as a reactant. Thus, if an inorganic chemical is represented by the formula AB in which A and B are atoms or groups and water is represented by the formula HOH, the hydrolysis reaction may be represented by the reversible chemical equation:

The reactants other than water, and the products of hydrolysis, may be neutral molecules (as in most hydrolysis reactions involving organic compounds) or ionic molecules (charged species), as in hydrolysis reactions of salts, acids, and bases.

In the reaction, the hydroxyl group replaces another chemical group on the inorganic molecule and hydrolysis reactions are usually catalyzed by hydrogen ions or hydroxyl ions. This produces the strong dependence on the acidity or alkalinity (pH) of the solution often observed but, in some cases, hydrolysis can occur in a neutral (pH = 7) environment. Adsorption on to a mineral sediment (such as a clay sediment that has strong adsorptive powers) generally reduces the rates of hydrolysis for acid- or base-catalyzed reactions. Neutral reactions appear to be unaffected by adsorption, although there is always the possibility that the mineral sediment can cause catalyzed chemical transformation reactions.

There are four possible general rules involving the reactions of salts in the aqueous environment: (i) if the salt is formed from a strong base and a strong acid, the salt solution is neutral, indicating that the bonds in the salt solution will not break apart (indicating no hydrolysis occurred) and is basic, (ii) if the salt is formed from a strong acid and weak base, the bonds in the salt solution will break apart and become acidic, (iii) if the salt is formed from a strong base and weak acid, the salt solution is basic and hydrolyzes, and (iv) if the salt is formed from a weak base and weak acid, it will hydrolyze but the acidity or basicity depends on the equilibrium constants of K_a and K_b . If the K_a value is greater than the K_b value, the resulting solution will be acidic and if the K_b value is greater than the K_a value, the resulting solution will be basic (Petrucchi et al., 2010).

Inorganic Chemical Transformation Reactions – Photolysis Reactions

Photolysis (also called photo-dissociation and photo-decomposition) is a chemical reaction in which an inorganic chemical (or an organic chemical) is broken down by photons and is the interaction of one or more photons with a target molecule. The photolysis reaction is not limited to the effects of visible light, but any photon with sufficient energy can cause the chemical transformation of the inorganic bonds of a chemical. Since the energy of a photon is inversely proportional to the wavelength, electromagnetic waves with the energy of visible light or higher, such as ultraviolet light, x-rays, and gamma rays, can also initiate photolysis reactions. The primary step of a photolysis reaction is:

X^* : an electronically excited state of molecule X and subsequently undergo either physical or chemical processes:

Physical processes:

Fluorescence:

Collisional deactivation:

Chemical processes:

Dissociation:

Isomerization:

Direct reaction:

Intramolecular rearrangement:

The general form of photolysis reactions:

The rate of reaction is:

$$-d/dt [X] = d/dt[Y] = d/dt[Z] = k[X]$$

K is the photolysis rate constant for this reaction in units of s^{-1} .

Photolysis occurs in the atmosphere as part of a series of reactions by which primary pollutant nitrogen oxides react to form secondary pollutants such as peroxyacyl nitrate derivatives. The two most important photolysis reactions in the troposphere are:

The excited oxygen atom (O^*) can react with water to give the hydroxyl radical:

The hydroxyl radical is central to atmospheric chemistry because it can initiate the oxidation of hydrocarbon derivatives in the atmosphere.

Another reaction involves the photolysis of nitrogen dioxide to produce nitric oxide and an oxygen radical that is a key reaction in the formation of tropospheric ozone:

The formation of the ozone layer is also caused by photolysis. Ozone in the stratosphere is created by ultraviolet light striking oxygen molecules (O_2) and splitting the oxygen molecules into individual oxygen atoms (atomic oxygen). The atomic oxygen then combines with unbroken an oxygen molecule to create ozone (O_3):

In addition, the absorption of radiation in the atmosphere can cause photo-dissociation of nitrogen (as one of several possible reactions) that can lead to the formation of nitric oxide (NO) and nitrogen dioxide (NO₂) that can act as a catalyst to destroy ozone:

As shown in the above equations, most photochemical transformations occur through a series of simple steps (Wayne, 2000; Wayne and Wayne, 2005).

Inorganic Chemical Transformation Reactions – Radioactive Decay

Radionuclides are inorganic chemicals that emit radiation because their atoms are unstable and they disintegrate or decay as they release energy in the form of radioactive particles or waves. There are many different types of radioactive decay. A decay, or loss of energy from the nucleus, results when an atom with an initial type of nucleus (the parent radionuclide or parent radioisotope) transforms into a daughter nuclide. The transformation produces an atom in a different state (a nucleus containing a different number of protons and neutrons). In some decay processes, the parent and the daughter nuclides are different chemical elements, and thus the decay process results in the creation of an atom of a different element (nuclear transmutation). Another type of radioactive decay results in products that are not defined, but appear in a range of molecular fragments of the original nucleus (spontaneous fission) which occurs when a large unstable nucleus spontaneously splits into two (and occasionally three) smaller daughter nuclei, and generally leads to the emission of gamma rays, neutrons, or other particles from those products.

Unlike other inorganic elements or chemicals, radionuclides degrade naturally, but the degradation process itself is hazardous to living things. The risk posed by radionuclides is a function of the type and amount of radiation, as well as exposure pathways. The half-life (the time required to reduce the concentration of a chemical to 50% of the initial concentration) of a radioactive element.

The radioactive half-life for a given radioisotope is a measure of the tendency of the nucleus to decay (disintegrate) and is based upon that probability. The half-life is independent of the physical state (solid, liquid, gas), temperature, pressure, the chemical compound in which the nucleus exists, and essentially any other outside influence. The half-life is also independent of the chemistry of the atomic surface, and independent of the ordinary physical factors of the environment in which the chemical exists.

Inorganic Chemical Transformation Reactions – Rearrangement Reactions

A rearrangement reaction falls into a broad class of (inorganic and organic) reactions where a molecule is rearranged to produce a structural isomer of the original molecule.

Inorganic reactions typically yield products that are in accordance with the generally-accepted mechanism of the reactions. However, in some instances, inorganic reactions do not give exclusively and solely the anticipated products but may lead to other product that arises from an unexpected and mechanistically different reaction path. This type

of unexpected product is often referred to as a rearranged product and, while such a product may not be the expected product, it may be the major product of the reaction. Thus, the reaction has involved a rearrangement of the expected product to an unexpected product – a rearrangement reaction has occurred. More than likely, this may have resulted from a plausible rearrangement occurring during the mechanistic course of the reaction to fulfill the principle of the minimum energy state of the whole system, that is, of the transition state which assumed another configuration to maintain a minimum energy balance to the system. In many cases, the rearrangement affords products of an isomerization, coupled with some stereochemical changes. An energetic requirement is also observed in order for a rearrangement to take place; that is, the rearrangement usually involves an evolution of energy (typically in the form of heat, i.e., the reaction is overall an exothermic reaction) evolution to be able to yield a more stable compound.

Inorganic Chemical Transformation Reactions – Redox Reactions

Redox reactions (reduction-oxidation reactions) are reactions in which one of the reactants is reduced and another reactant is oxidized. Therefore, the oxidation state of the species involved must change. The word reduction originally referred to the loss in weight upon heating a metallic ore such as a metal oxide to extract the metal – the ore was reduced to the metal. However, the meaning of reduction has become generalized to include all processes involving gain of electrons. Thus, in redox reactions, one chemical is oxidized while another chemical is reduced by the net transfer of electron from one chemical to the other. As may be expected, the change in the oxidation states of the oxidized species must be balanced by any changes in the reduced species. For example, the production of iron from the iron oxide ore:

To complicate matters even further, the oxidizing and reducing agents can be the same element or compound, as is the case when disproportionation of the reactive species occurs. For example:

In this equation, n is the number of electrons transferred. Disproportionation reactions do not need to commence with a neutral molecule and can involve more than two species with differing oxidation states.

Within redox reactions, the pair of reactions must always occur, i.e., a reduction reaction must be accompanied by an oxidation process, as electrons are transferred from one chemical to another. Each of the singular reactions in this pair is often referred to as a half-reaction, in which the electrons lost or gained are included explicitly, allowing the electron balance to be counted. The two sides of the reaction, given by the half reactions, should be balanced accordingly. The additional terminology comes from the definition that within redox processes, a reductant transfers electrons to an oxidant, hence, the reductant (reducing agent) loses electrons, so is oxidized, while the oxidant (oxidizing agent) gains electrons, so is reduced.

Inorganic Matter

The inorganic component (mineral matter) of the soil is composed of many types of minerals which influence the properties of the soil. The inorganic material of soil is composed of rock, slowly broken down into smaller particles that vary in size. Soil particles that are 0.1 to 2 mm in diameter are sand. Soil particles between 0.002 and 0.1 mm are called silt, and even smaller particles, less than 0.002 mm in diameter, are called clay. Some soils have no dominant particle size, containing a mixture of sand, silt, and humus; this type of soil is generally referred to as loam.

The weathering of parent rocks and minerals to form the inorganic soil components results ultimately in the formation of inorganic colloids. These colloids are repositories of water and plant nutrients, which may be made available to plants as needed. Inorganic soil colloids often absorb toxic substances in soil, thus playing a role in

detoxification of substances that otherwise would harm plants. The abundance and nature of inorganic colloidal material in soil are obviously important factors in determining soil productivity.

The uptake of plant nutrients by roots involves interactions with the water and inorganic phases. For example, a nutrient held by an inorganic colloid material has to traverse the mineral/water interface and then the water/root interface. This process is often strongly influenced by the ionic structure of soil inorganic matter.

Most common elements in the crust of the Earth are oxygen, silicon, aluminum, iron, calcium, sodium, potassium, and magnesium. Therefore, minerals composed of these elements (particularly silicon and oxygen) constitute most of the mineral fraction of the soil. Common soil mineral constituents are finely divided quartz (SiO_2), orthoclase (KAlSi_3O_8), albite [$\text{NaAlSi}_3\text{O}_8$], epidote [$4\text{CaO}_3(\text{AlFe})_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot \text{H}_2\text{O}$], goethite [$\text{FeO}(\text{OH})$], magnetite (Fe_3O_4), calcium carbonate (CaCO_3) and dolomite, the mixed calcium and magnesium carbonates ($\text{CaCO}_3 \cdot \text{MgCO}_3$), and oxides of manganese (MnO) and titanium (TiO).

Instability and Incompatibility

In general, fuel instability and fuel incompatibility can be related to the heteroatom-containing compounds (i.e., nitrogen-, oxygen-, and sulfur-containing compounds) that are present. The degree of unsaturation of the fuel (i.e., the level of olefin species) also plays a role in determining instability/incompatibility. The instability/incompatibility of fuels (from a variety of sources) is manifested in the formation of sludge, sediment, and general darkening in color of the liquid (ASTM D1500).

Sludge (or sediment) formation takes one of the following forms (i) material dissolved in the liquid, (ii) precipitated material, and (iii) material emulsified in the liquid. Under favorable conditions, sludge or sediment will dissolve in the crude oil or product with the potential of increasing the viscosity. Sludge or sediment, which is not soluble in the fuel (ASTM D96, ASTM D473, ASTM D1796, ASTM D2273, ASTM D4007, ASTM D4807, ASTM D4870), may either settle at the bottom of the storage tanks or remain in the crude oil as an emulsion. In most of the cases, the smaller part of the sludge/sediment will settle satisfactorily; the larger part will stay in the liquid as an emulsion. In any case, there is a need of breaking the emulsion, whether it is a water-in-oil emulsion or whether it is the sludge itself, which has to be separated into the oily phase and the aqueous phase. The oily phase can be then processed with the crude oil, and the aqueous phase can be drained out of the system.

Phase separation can be accomplished by either the use of suitable surface active agents allowing for sufficient settling time, or by use of a high voltage electric field for breaking such emulsions after admixing water at a rate of approximately 5% and at a temperature of approximately 100°C (212°F).

Thus, fuels are typically incompatible when sludge, semi-solid, or solid particles (for convenience here, these are termed secondary products to distinguish them from the actual fuel) are formed during and after blending. This phenomenon usually occurs prior to use. If the secondary products are marginally soluble in the blended product, use might detract from solubility of the secondary products and they will appear as sludge or sediment that can be separated by filtration or by extraction (ASTM D4310). When the secondary products are truly insoluble, they separate and settle out as a semi-solid or solid phase floating in the fuel or are deposited on the walls and floors of containers. In addition, secondary products usually increase the viscosity of the crude oil product. Standing at low temperatures will also cause a viscosity change in certain fuels (ASTM D2532).

Instability and Incompatibility – Methods For Determining

Stability/instability and compatibility/incompatibility can be estimated using several tests. These tests are:

1. Compatibility spot tests (ASTM D2781, ASTM D4740).
2. Thermal stability test data (ASTM D873, ASTM D3241).
3. Existent and potential sludge formation (hot filtration test) (ASTM D4870).
4. Asphaltene content (ASTM D3729).

5. The rate of viscosity increase (ASTM D445) of stored residual fuel oil samples at various temperatures with and without exposure to air.
6. Color (ASTM D1500).

In addition to the test for the stability and compatibility of fuels (ASTM D4740), the other most frequently stability test used is the existent and accelerated dry sludge content determination of residual fuels (the hot filtration test). Hot filtration test results of up to 0.2% w/w are considered to be satisfactory; results above 0.4% w/w indicate a poor stability, but differing values might be required, depending on the intended use of the product.

One test, or property, that is somewhat abstract in its application but which is becoming more meaningful popular is the solubility parameter. The solubility parameter allows estimations to be made of the ability of liquids to become miscible on the basis of miscibility of model compound types where the solubility parameter can be measured or calculated.

Although the solubility parameter is often difficult to define when complex mixtures are involved, there has been some progress. For example, crude oil fractions have been assigned a similar solubility parameter to that of the solvent used in the separation. However, there is also the concept that the solubility parameter of crude oil fractions may be defined somewhat differently insofar as they can be estimated from data such as the atomic hydrogen-to-carbon ratios. Whichever method is the best estimate may be immaterial as long as the data are used to the most appropriate benefit and allow some measure of predictability.

Bottle tests constitute the predominant test method, and the test conditions have varied in volume, type of glass or metal, vented and unvented containers, and type of bottle closure. Other procedures have involved stirred reactor vessels under both air pressure or under oxygen pressure, and small volumes of fuel employing a cover slip for solid deposition (ASTM D4625). All of these procedures are gravimetric in nature.

There are several accelerated fuel stability tests that can be represented as a time-temperature matrix. A graphical representation shows that the majority of the stability tests depicted fall close to the solid line, which represents a doubling of test time for each 10°C (18°F) change in temperature. The line extrapolates to approximately one year of storage under ambient conditions. Temperatures at 100°C (212°F) or higher present special chemical problems.

The heteroatom content of the deposits formed in stability studies varied as the source or type of dopant and fuel liquid source varied. This would be an anticipated result. The color changes of both the fuel and the deposits formed are more difficult to interpret.

It is also worthy of note that fractionation of crude oil and its products may also give some indication of instability. There are many schemes by which crude oil and related materials might be fractionated.

There is a series of characterization indices that are present indications of whether or not a crude oil product is stable or unstable. For example, the characterization factor indicates the chemical character of the crude oil and has been used to indicate whether a crude oil was paraffinic in nature or whether it was a naphthenic/aromatic crude oil.

The characterization factor (sometimes referred to as the Watson characterization factor) is a relationship between boiling point and specific gravity:

$$K = T_b^{1/3}/d$$

T_b is the cubic average boiling point, degrees Rankine (°F + 460), and d is the specific gravity at 15.6°C (60°F).

The characterization factor was originally devised to illustrate the characteristics of various feedstocks. Highly paraffinic oils have $K = 12.5$ -13.0, while naphthenic oils have $K = 10.5$ -12.5. In addition, if the characterization factor is above 12, the liquid fuel or product might, because of its paraffinic nature, be expected to form waxy deposits during storage.

Iodine Number

The iodine number (iodine value) is a measure of the iodine absorption by oil under standard conditions and is used to indicate the quantity of unsaturated compounds present. The test method (ASTM D2078) is included in some

specifications and is a measure of fatty acid components or unsaturation either as olefins and/or aromatics. The former are very unlikely to be present in any oil that has undergone sufficient refining to make it colorless, while the aromatic content can be controlled by setting a suitable value for the ultra-violet absorption.

In the test method (ASTM D2078), a sample is dissolved in chloroform and reacted with Wijs solution for 30 minutes in the dark at 25°C. At the end, the solution is mixed with potassium iodide (KI) and titrated with sodium thiosulfate using starch indicator and compared to a blank determination.

Ionic Liquids

An ionic liquid has been defined as a salt that is in the liquid state at ambient temperature, but another definition is that an ionic liquid is a liquid comprised entirely of ions. In fact, any salt that melts without decomposing or vaporizing usually yields an ionic liquid. For example, sodium chloride (NaCl) melts at 801°C (1,474°F) into a liquid that consists largely of sodium cations (Na⁺) and chloride anions (Cl⁻). Conversely, when an ionic liquid is cooled, it often forms an ionic solid which may be either a crystalline solid or a glassy solid. Furthermore, the choice of the cation has a strong impact on the properties of the ionic liquid and will often define the stability. The chemistry and functionality of the ionic liquid is, in general, controlled by the choice of the anion. Free acid of the appropriate anion.

The synthesis of ionic liquids can generally be split into two sections: the formation of the desired cation, and anion exchange where necessary to form the desired product. In some cases, only the first step is required.

Cations synthesis may be carried out either by protonation with a free acid or by quaternarization of an amine or a phosphine, most commonly with an alkyl halogen compound. Alkylation reaction may be carried out with haloalkane derivatives, bromo-alkane derivative derivatives, and iodo-alkane derivative derivatives, with the required reaction conditions becoming less severe in the order Cl < Br < I. The reactivity of the haloalkane also generally decreases with increasing alkyl chain length. The alkylation process possesses the advantages that a wide range of cheap haloalkanes are available, and the substitution reactions generally occur smoothly at even-handed temperatures. Furthermore, the halide salts formed can easily be converted into salts with other anions.

Anion-exchange reactions of ionic liquids can really be divided into two distinct categories which are (i) the direct treatment of halide salts with Lewis acids, and (ii) the formation of ionic liquids by anion metathesis.

The main goal of all anion exchange reactions is the formation of the desired ionic liquid uncontaminated with unwanted cations or anions, a task that is easier for water-immiscible ionic liquids. The synthesis of second-generation ionic liquids, air-stable and water-stable ionic liquids, involved a metathesis reaction between imidazolium halide and a range of silver salts (such as silver nitrate, AgNO₃, silver borofluoride, AgBF₄, silver acetate, AgCH₃CO₂, and silver sulfate, Ag₂SO₄ in methanol or in aqueous methanol solution). The low solubility of silver halide (iodide is the lowest soluble) in these solvents allowed it to be separated simply by filtration, and removal of the reaction solvent allowed isolation of the ionic liquids in high yields and purity. This method has been touted as the most efficient for the synthesis of water-miscible ionic liquids. Complete precipitation of silver halides from organic solvents can also be slow, leading to silver-contaminated products.

Among the various classes of ionic liquids, those containing *N*-heterocyclic cations are most widely used. Imidazolium salts represent the most prominent subclass in this area, and a number of them are commercially available. The solvent properties such as melting points, solubility, and viscosity can easily be tuned in a wide range by varying the substituents at the nitrogen atoms as well as by varying the counter-ions. This makes ionic liquids in general, real designer solvents. Even if imidazolium salts have found very wide application in organic synthesis and catalysis, they have some limitations. One important limitation is that they do not behave as innocent solvents under strongly basic conditions, where they suffer from deprotonation at a carbon atom leading to *N*-heterocyclic carbenes. 1,2,3-Triazolium salts lack an acidic ring-carbon flanked by two nitrogen atoms; consequently, they should be advantageous in this aspect. Unlike 1,2,4-triazolium salts, 1,2,3-triazolium salts were neglected as potential ionic liquids until recently.

In terms of the properties of ionic liquids (Table I-2), they are often moderate-to-poor conductors of electricity, non-ionizing, highly viscous, and frequently exhibit low vapor pressure. The other properties are diverse; for example, many ionic liquids have low combustibility, are thermally stable, with wide liquid regions, and have favorable solvating properties for a range of polar and non-polar compounds.

Table I-2 General properties of ionic liquids.

Property	Comment
A salt	Cation is usually large
A salt	Anion is usually small
Melting point	Preferably below 100°C
Freezing point	Preferably below 100°C
Liquid range	>200°C
Thermal stability	High
Viscosity	<100 cP
Dielectric constant	<30
Polarity	Moderate
Solvent properties	Good
Catalytic properties	Good
Vapor pressure	Low-to-negligible

In the energy field, ionic liquids have many potential applications, such as they are powerful solvents and can be used as electrolytes (Table I-3). In fact, salts that are liquid at near-ambient temperature are important for electric battery applications.

Also, the ionic liquid 1-butyl-3-methylimidazolium chloride has been investigated for the recovery of uranium and other metals from spent nuclear fuel and other sources. Protonated betaine bis(trifluoro-methane sulfonyl) imide has been investigated as a solvent for uranium oxides. The ionic liquids, n-butyl-n-methyl pyrrolidinium bis(trifluoro methyl sulfonyl)imide and n-methyl-n-propyl piperidinium bis(trifluoromethyl sulfonyl)imide, have been investigated for the electrodeposition of europium and uranium metals, respectively.

Ionic liquids are also potential heat transfer and storage media in solar thermal energy systems. Concentrating solar thermal facilities such as parabolic troughs and solar power towers focus the sun's energy onto a receiver which can generate temperatures on the order of around 600°C (1,110°F). This heat can then generate electricity in a steam or other cycle. For buffering during cloudy periods or to enable generation overnight, energy can be stored by heating an intermediate fluid. Although nitrate salts have been the medium of choice since the early 1980s, they freeze at a temperature on the order of 220°C (430°F) and thus require heating to prevent solidification.

Ionic liquids can aid the recycling of synthetic goods, plastics, and metals and offer the specificity required to separate similar compounds from each other, such as separating polymeric substances from plastic waste streams which can help avoid incinerating plastics or discharging them in a landfill.

However, while the low volatility of ionic liquids eliminates a major pathway for environmental release and contamination, the aquatic toxicity of ionic liquids is at least as severe (or even more so) than many solvents. Moreover, balancing the reduction of volatile organic compounds (VOCs) against waterway spills (via waste ponds/streams) requires caution because the diversity of ionic liquids simplifies the process of identifying compounds that meet safety requirements.

Iogen Process

The production of alcohol for fuels (as well as for petrochemical uses) from cellulosic biomass is of growing interest around the world. Cellulosic biomass can be used to produce transportation fuel, with the overall process having little net production of greenhouse gases. Biomass is available as a by-product of many industrial processes and agricultural materials, or can be potentially produced from dedicated energy crops.

The Iogen process is an enzymatic hydrolysis process for converting lignocellulose materials to ethanol. The unique aspects of the technology include the steam explosion pre-treatment that was pioneered by Iogen, and the proprietary enzymes developed, manufactured, and marketed by Iogen. The cellulose hydrolysis is an expensive but effective option and not economically feasible for all ethanol producers.

The process is currently suitable for agricultural residues such as wheat straw and corn straw. Hardwood residues are also a suitable feedstock. A single step pre-treatment process for agricultural and hardwood residues can produce a material that can be efficiently hydrolyzed by the enzymes. The pre-treatment process is not as effective for separating the lignin of softwoods from the cellulosic material.

The process will produce lignin as a co-product. The relatively mild pre-treatment process employed should provide a lignin that can be utilized as a starting material in other processes.

Iron Oxide Process

The iron oxide process (iron sponge process, dry box process) is the oldest and most widely used batch process for sweetening of natural gas and natural gas liquids. The process was implemented during the 19th century and has been in use in Europe and the United States for over 100 years. Hydrogen sulfide scavengers are appropriate for use at the low concentrations of hydrogen sulfide where conventional chemical absorption and physical solvents are not economical.

In the process, gas is passed through a bed of wood chips impregnated with iron oxide to scavenge hydrogen sulfide and organic sulfur compounds (mercaptans) from natural gas streams. The iron sponge method is a semi-continuous system employing two steel drums as main equipment, packed with wood shavings impregnated with iron oxide.

The iron sponge process is considered a selective process removing only hydrogen sulfide and small traces of carbonyl sulfide and carbon disulfide. The basis of the operation is the chemical reaction of the H_2S content in the stream with the hydrated iron oxide to form iron sulfide.

The *sponge* consists of wood shavings impregnated with a hydrated form of iron oxide. The wood shavings serve as a carrier for the active iron oxide powder. Hydrogen sulfide is removed by reacting with iron oxide to form ferric sulfide. The process is usually best applied to gases containing low-to-medium concentrations (300 ppm) of hydrogen sulfide or mercaptans. This process tends to be highly selective and does not normally remove significant quantities of carbon dioxide. As a result, the hydrogen sulfide stream from the process is high purity. The use of iron sponge process for sweetening sour gas is based on adsorption of the acid gases on the surface of the solid sweetening agent followed by chemical reaction of ferric oxide (Fe_2O_3) with hydrogen sulfide:

The reaction requires the presence of slightly alkaline water and a temperature below 43°C (110°F), and bed alkalinity should be checked regularly, usually on a daily basis. A pH level on the order of 8-10 should be maintained through the injection of caustic soda with the water. If the gas does not contain sufficient water vapor, water may need to be injected into the inlet gas stream.

The ferric sulfide produced by the reaction of hydrogen sulfide with ferric oxide can be oxidized with air to produce sulfur and regenerate the ferric oxide:

The regeneration step, i.e., the reaction with oxygen is exothermic and air must be introduced slowly so the heat of reaction can be dissipated. If air is introduced quickly, the heat of reaction may ignite the bed. Some of the elemental sulfur produced in the regeneration step remains in the bed. After several cycles, this sulfur will form a cake over the ferric oxide, decreasing the reactivity of the bed. Typically, after 10 cycles, the bed must be removed and a new bed introduced into the vessel.

In some designs, the iron sponge may be operated with continuous regeneration by injecting a small amount of air into the sour gas feed. The air regenerates ferric sulfide, while hydrogen sulfide is removed by ferric oxide. This process is not as effective at regenerating the bed as the batch process and requires a higher-pressure air stream.

In the process, the sour gas should pass down through the bed. In the case where continuous regeneration is to be utilized, a small concentration of air is added to the sour gas before it is processed. This air serves to continuously regenerate the iron oxide, which has reacted with hydrogen sulfide, which serves to extend the on-stream life of a given tower but probably serves to decrease the total amount of sulfur that a given weight of bed will remove. The number of vessels containing iron oxide can vary from one to four. In a two-vessel process, one of the vessels would be on stream removing hydrogen sulfide from the sour gas while the second vessel would either be in the regeneration cycle or having the iron sponge bed replaced.

When periodic regeneration is used, a tower is operated until the bed is saturated with sulfur and hydrogen sulfide begins to appear in the sweetened gas stream. At this point, the vessel is removed from service and air is circulated through the bed to regenerate the iron oxide. Regardless of the type of regeneration process used, a given iron oxide bed will lose activity gradually and eventually will be replaced. For this reason, the reactor vessels should be designed to minimize difficulties in replacing the iron sponge in the beds. The change out of the beds is hazardous. Exposure to air when dumping a bed can cause a sharp rise in temperature, which can result in spontaneous combustion of the bed. Care must be exercised in opening the tower to the air. The entire bed should be wetted before beginning the change out operation.

Iron oxide reactors have taken on a number of configurations from conventional box vessels to static tower purifiers. The selection depends upon the process application. Static tower purifiers are used in high-pressure applications,

since a longer bed depth gives a greater efficiency, and the total pressure drop is a smaller fraction of the available pressure. Static tower purifiers are also fitted with trays to eliminate compaction for lower-pressure applications. Conventional boxes consist of large rectangular vessels, either built into the ground, or supported on legs to save footprint. They are composed of several layers, with a typical bed depth of at least two feet.

Iron oxide suspensions, like iron oxide slurries, rely upon hydrated ferric oxide as the active regenerable agent. However, iron oxide suspensions react in a basic environment with an alkaline compound, followed by the reaction of the hydrosulfide with iron oxide to form iron sulfide. The iron is then regenerated by aeration.

Generally, the iron oxide process is suitable only for small-to-moderate quantities of hydrogen sulfide. Approximately 90% of the hydrogen sulfide can be removed per bed, but bed clogging by elemental sulfur occurs, and the bed must be discarded, and the use of several beds in series is not usually economical. Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the Ferrox process or the Stretford process. The *Ferrox process* is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

The gas stream should be wet when passing through an iron sponge bed as drying of the bed will cause the iron sponge to lose its capacity for reactivity. If the gas is not already water-saturated or if the influent stream has a temperature greater than 50°C (approximately 120°F), water with soda ash is sprayed into the top of the contactor to maintain the desired moisture and alkaline conditions during operation.

During recent years, hydrogen sulfide scavenger technology has been expanded with many new materials coming on the market and others being discontinued. Overall, the simplicity of the process, low capital costs, and relatively low chemical (iron oxide) cost continue to make the process an ideal solution for hydrogen sulfide removal.

Iron Oxide Slurry Process

The process is designed to remove hydrogen sulfide from natural gas streams and uses iron oxide powder suspended in an aqueous column. Hydrogen sulfide in the gas stream reacts with the iron oxide as the gas stream is bubbled up through the suspension. The reactions of the iron oxide slurry are similar to those for dry iron oxide processes, except with a higher proportion of the magnetite form of iron oxide (Fe_3O_4) (Slurrisweet process).

An iron oxide slurry was used in conjunction with a silicon-based defoamer with additives and a dispersant to reduce potential problems due to foaming, rapid settling of suspended iron oxide particles, and short batch life. Corrosion was inhibited by using an epoxy coating on the vessel. Injection of air at 5% mole concentration of hydrogen sulfide extended the batch life and stabilized the spent chemical.

Advantages of the process include its ability to selectively remove hydrogen sulfide from a natural gas stream containing carbon dioxide. Furthermore, the process offers a scheme of sweetening without the undesirable side effects of emission of sulfur dioxide and spent batch disposal problems.

However, there are disadvantages of the slurry process that relate to: (i) carry-over of oxide slurry from the contactor tower, (ii) occasional failure of a fresh slurry batch to sweeten below the hydrogen sulfide sale gas sales specification, (iii) inconsistent and short batch life, (iv) rapid settling of oxide powder at low production rates, (v) inability to remove all of spent slurry solids from contactor, leaving plugged tower packing and promoting subsequent channeling of gas, and (vi) fouling of valve seats and plugging small lines.

These disadvantages can be eliminated by employing both mechanical and chemical alterations. Additives have been shown to be effective in eliminating carry-over improving the suspension properties of the slurry oxide. This also allows for better removal of expended slurry solids during batch change outs. Controlled injection of trace amounts of air into the sour gas stream has resulted in substantially longer slurry batch life and considerably lower hydrogen sulfide in the product gas.

Iron Oxide Suspension Process

Iron oxide suspensions, like iron oxide slurries, rely upon hydrated ferric oxide as the active regenerable agent. However, iron oxide suspensions react in a basic environment with an alkaline compound, followed by the reaction of the hydrosulfide with iron oxide to form iron sulfide; the iron is then regenerated by aeration.

Iron oxide suspensions are the precursors to the chelated iron used in iron chelate solutions for chelate processes.

Iron Sponge Process

Hydrogen sulfide scavengers have been used for many years. An example is the iron sponge process (*iron oxide process, dry box process*) that is the oldest and still the most widely used batch process for sweetening of natural gas and natural gas liquids. The process was implemented during the 19th century and has been in use in Europe and the United States for over 100 years. Hydrogen sulfide scavengers are appropriate for use at the low concentrations of hydrogen sulfide where conventional chemical absorption and physical solvents are not economical. During recent years, hydrogen sulfide scavenger technology has been expanded with many new materials coming on the market and others being discontinued. Overall, the simplicity of the process, low capital costs, and relatively low chemical (iron oxide) cost continue to make the process an ideal solution for hydrogen sulfide removal.

The *sponge* consists of wood shavings impregnated with a hydrated form of iron oxide. The wood shavings serve as a carrier for the active iron oxide powder. Hydrogen sulfide is removed by reacting with iron oxide to form ferric sulfide. The process is usually best applied to gases containing low-to-medium concentrations (300 ppm) of hydrogen sulfide or mercaptans. This process tends to be highly selective and does not normally remove significant quantities of carbon dioxide. As a result, the hydrogen sulfide stream from the process is high purity. The use of iron sponge process for sweetening sour gas is based on adsorption of the acid gases on the surface of the solid sweetening agent followed by chemical reaction of ferric oxide (Fe_2O_3) with hydrogen sulfide:

The reaction requires the presence of slightly alkaline water and a temperature below 43°C (110°F), and bed alkalinity should be checked regularly, usually on a daily basis. A pH level on the order of 8-10 should be maintained through the injection of caustic soda with the water. If the gas does not contain sufficient water vapor, water may need to be injected into the inlet gas stream.

The ferric sulfide produced by the reaction of hydrogen sulfide with ferric oxide can be oxidized with air to produce sulfur and regenerate the ferric oxide:

The regeneration step, i.e., the reaction with oxygen is exothermic, and air must be introduced slowly so the heat of reaction can be dissipated. If air is introduced quickly, the heat of reaction may ignite the bed. Some of the elemental sulfur produced in the regeneration step remains in the bed. After several cycles, this sulfur will form a cake

over the ferric oxide, decreasing the reactivity of the bed. Typically, after 10 cycles, the bed must be removed and a new bed introduced into the vessel.

In the process, the sour gas should pass down through the bed. In the case where continuous regeneration is to be utilized, a small concentration of air is added to the sour gas before it is processed. This air serves to continuously regenerate the iron oxide, which has reacted with hydrogen sulfide, which serves to extend the on-stream life of a given tower but probably serves to decrease the total amount of sulfur that a given weight of bed will remove. In some designs, the iron sponge may be operated with continuous regeneration by injecting a small amount of air into the sour gas feed. The air regenerates ferric sulfide while hydrogen sulfide is removed by ferric oxide. This process is not as effective at regenerating the bed as the batch process and requires a higher-pressure air stream. Also, the number of vessels containing iron oxide can vary from one to four. In a two-vessel process, one of the vessels would be on stream removing hydrogen sulfide from the sour gas, while the second vessel would either be in the regeneration cycle or having the iron sponge bed replaced.

When periodic regeneration is used, a tower is operated until the bed is saturated with sulfur and hydrogen sulfide begins to appear in the sweetened gas stream. At this point, the vessel is removed from service and air is circulated through the bed to regenerate the iron oxide. Regardless of the type of regeneration process used, a given iron oxide bed will lose activity gradually and eventually will be replaced. For this reason, the reactor vessels should be designed to minimize difficulties in replacing the iron sponge in the beds. The change out of the beds is hazardous. Exposure to air when dumping a bed can cause a sharp rise in temperature, which can result in spontaneous combustion of the bed. Care must be exercised in opening the tower to the air. The entire bed should be wetted before beginning the change out operation.

Iron oxide reactors have taken on a number of configurations from conventional box vessels to static tower purifiers. The selection depends upon the process application. Static tower purifiers are used in high-pressure applications, since a longer bed depth gives a greater efficiency, and the total pressure drop is a smaller fraction of the available pressure. Static tower purifiers are also fitted with trays to eliminate compaction for lower-pressure applications. Conventional reactors consist of large rectangular vessels, either built into the ground, or supported on legs to save footprint. They are composed of several layers, with a typical bed depth of at least two feet.

Iron oxide suspensions, like iron oxide slurries, rely upon hydrated ferric oxide as the active regenerable agent. However, iron oxide suspensions react in a basic environment with an alkaline compound, followed by the reaction of the hydrosulfide with iron oxide to form iron sulfide. The iron is then regenerated by aeration.

Generally, the iron oxide process is suitable only for small-to-moderate quantities of hydrogen sulfide. Approximately 90% of the hydrogen sulfide can be removed per bed, but bed clogging by elemental sulfur occurs and the bed must be discarded and the use of several beds in series is not usually economical. Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the Ferrox process or the Stretford process. The *Ferrox process* is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

The natural gas should be wet when passing through an iron sponge bed as drying of the bed will cause the iron sponge to lose its capacity for reactivity. If the gas is not already water-saturated or if the influent stream has a temperature greater than 50°C (approximately 120°F), water with soda ash is sprayed into the top of the contactor to maintain the desired moisture and alkaline conditions during operation.

Isotopes

The term isotope is a form of a chemical element that is characterized by the same number of protons but different numbers of neutrons in their nucleus. An isotope shares the same atomic number and location in the periodic table, but have distinct atomic weights.

Thus, an isotope is an atom of an element that have the usual number of protons but different numbers of neutrons in their nuclei. For example, twelve protons and twelve neutrons make up the nucleus of the element carbon. One isotope of carbon, C-14, has twelve protons and fourteen neutrons in its nucleus.

Using hydrogen as the example, there are three isotopes of the element which are (i) hydrogen, (ii), deuterium, and (iii) tritium. How do we distinguish between them which each have one single proton but differ in the number of the neutrons? Hydrogen has no neutron, deuterium has one neutron, and tritium has two neutrons. Some elements, such as carbon, potassium, and uranium, have naturally occurring isotopes. Carbon-12 (^{12}C), the most common isotope of carbon, contains six protons and six neutrons.

Radioisotopes such as carbon-14 (C-14, ^{14}C) are unstable isotopes, and the nuclei of such isotopes decay (break apart) at a steady rate. Decaying radioisotopes produce other isotopes as they emit energy and/or high-energy particles. If the newly formed nuclei are radioactive as well, they emit radiation and change into other nuclei. The final products in this chain are stable, nonradioactive nuclei.

ITSL Process

The integrated two-stage liquefaction process (ITSL process) has received considerable attention as one of the most promising technology indirect coal liquefaction.

The process consists of a slurry preparation step and followed by hydrotreated solvent recovery and a solvent deashing system. The system was integrated by the recycle of the resid, hydrotreated solvent, and low-pressure flash bottoms containing ash, unconverted coal, hydrotreated resid, and hydrotreated solvent. Solids recycle allows an increased concentration of solids in the feedstock and hence a lower feed rate. The solvent recovery system consists of atmospheric flash and vacuum flash equipment.

The process lends itself to the conversion of biomass (either alone or with a carbonaceous feedstock such as coal) to fuel products, and the biomass can also be used as a hydrogen source via gasification to compensate for the any deficit in process hydrogen.

See also: Gasification, Gasification of Biomass.

Jatropha

Jatropha is a small but versatile bush/tree from the Euphorbiaceae family. The tree flowers and produces clusters of approximately 10 to 15 fruits with a seed containing high concentrations of oil. *Jatropha curcas* L. is gaining a lot of attention as a potential feedstock for biodiesel production due to its high oil content and ability to grow in less than ideal conditions. However, harvesting and logistical challenges have kept the plant from being grown in large-scale production in places where there is not an abundance of low-cost labor. Historically, most of the Jatropha has been grown in tropical areas including Africa and Asia, especially India. More recently, it has been grown on most continents around the world. The green shading on the map below indicates the primary areas where Jatropha is grown. These areas are mainly inside the tropics and are not known to have land of good quality.

This low maintenance plant has generally proven to be resistant to local pests under common cultivation practices and can produce seeds containing up to 40% oil. While Jatropha is touted as being able to survive in poor soils with only small amounts of fertilizer and water; the fruit (and thus oil) yields increase significantly with increased soil fertility and water. For example, adding small amounts of magnesium, sulfur, and calcium have a significant impact on improving yields. Jatropha can survive in areas with annual rainfall of 8 to 12 inches. In extreme conditions, plants will survive drought by dropping its leaves to reduce transpiration loss. In fact, this resilient plant can survive three full years of drought before it would die. However, fruit production is low to minimal during these drought years. While Jatropha is most commonly grown in low altitude regions that are relatively warm, it can grow at higher altitudes but can only handle a slight frost.

Jatropha Oil

The use of biodiesel as an alternative fuel is becoming increasingly popular, and the interest in using Jatropha as a non-edible oil feedstock is rapidly growing. Jatropha oil is vegetable oil produced from the seeds of the *Jatropha curcas*, a plant that can grow in marginal lands and common lands. When Jatropha seeds are crushed, the resulting Jatropha oil can be processed to produce a high-quality biodiesel that can be used in a standard diesel car, while the residue (press cake) can also be processed and used as biomass feedstock to power electricity plants or used as fertilizer (it contains nitrogen, phosphorus, and potassium). The plant may yield more than four times as much fuel per acre as soybean, and more than ten times that of maize (corn).

Jatropha curcas is considered to be as one of the best candidates for future biodiesel production. The performance of the engine using blends of diesel and Jatropha oil and significant improvement in performance of a single cylinder was observed compared to vegetable oil alone. The specific fuel consumption and the exhaust gas temperature were reduced due to decrease in viscosity of the vegetable oil. Acceptable thermal efficiencies of the engine were obtained with blends containing up to 50% volume of Jatropha oil. From the properties and engine test results, a 40 to 50% v/v blend of Jatropha oil can be substituted for diesel without any engine modification.

Different methods can be used to obtain Jatropha oil from the seeds – the common methods used for the extraction of the oil include (i) mechanical pressing, (ii) supercritical fluid extraction, and (iv) solvent extraction. Biodiesel is produced from Jatropha oil by transesterification which involves altering the chemical properties of a vegetable oil by using methanol. Transesterification of vegetable oil is a relatively simple process that yields high conversion with glycerin as the only by-product.

Jerusalem Artichoke

The Jerusalem artichoke (*Helianthus tuberosus*, also called sunroot, sunchoke, or earth apple) is a species of sunflower that is native to central North America. It is a herbaceous perennial plant that grows up to 5 to 10 feet tall with opposite leaves on the upper part of the stem but alternate below. The leaves have a rough, hairy texture. Larger leaves on the lower stem are broad-ovoid-acute and can be up to 12 inches long, while the leaves higher on the stem are smaller and narrower. The tubers are often elongated and uneven, typically 3 to 4 inches long and 1 to 2 inches thick with a crisp and crunchy texture when raw. They vary in color from pale brown to white, red, or purple.

The Jerusalem artichoke has shown excellent potential as an alternative sugar crop. A member of the sunflower family, this crop is native to North America and well-adapted to northern climates. Like the sugar beet, the Jerusalem artichoke produces sugar in the top growth and stores it in the roots and tuber. It can grow in a variety of soils, and it is not demanding of soil fertility. The Jerusalem artichoke is a perennial; small tubers left in the field will produce the next seasonal crop, so no ploughing or seeding is necessary. The high-fructose syrups that can be derived from the tubers produced by the *Jerusalem artichoke* may be used for the production of ethanol and other industrial raw materials. Jerusalem artichokes also produce a large amount of top growth which may also prove to be a useful source of biomass for energy purposes.

The crop is relatively easy to grow but difficult to harvest and store. The tubers are tightly attached to the crown of the plant and, when dug by machine, come up as a mass of tubers, crown tissue, and soil which does not separate well like potato or sweet potato. Thus, much hand labor was needed for harvest. In addition to that, the tubers do not store well after digging and must be utilized quickly to prevent spoilage and loss. However, the tubers do keep well in the soil and presumably could be stored in the field and dug as needed whenever the soil was not too wet.

Kerosene

Kerosene (kerosine; lamp oil), also called paraffin or paraffin oil, is a flammable pale-yellow or colorless oily liquid with a characteristic odor. It is obtained from petroleum and used for burning in lamps and domestic heaters or furnaces, as a fuel or fuel component for diesel fuel and jet fuel, and as a solvent for greases and insecticides.

Kerosene is intermediate in volatility between gasoline and gas/diesel oil. It is a medium-boiling oil distilling between 150 and 300°C (300 to 570°F). Kerosene has a flash point about 25°C (77°F) and is suitable for use as an illuminant when burned in a wide lamp. The term *kerosene* is also too often incorrectly applied to various fuel oils, but a fuel oil is actually any liquid or liquid petroleum product that produces heat when burned in a suitable container or that produces power when burned in an engine.

Kerosene was the major refinery product before the onset of the *automobile age*, but now kerosene can be termed one of several secondary petroleum products after the primary refinery product – gasoline. Kerosene originated as a straight-run petroleum fraction that boiled between approximately 205 and 260°C (400 to 500°F). Some crude oils, for example those from the Pennsylvania oil fields, contain kerosene fractions of high quality, but other crude oils, such as those having an asphalt base, must be thoroughly refined to remove aromatics and sulfur compounds before a satisfactory kerosene fraction can be obtained.

Composition

Chemically, kerosene is a mixture of hydrocarbons; the chemical composition depends on its source, but it usually consists of about 10 different hydrocarbons, each containing from 10 to 16 carbon atoms per molecule; the constituents include *n*-dodecane ($n\text{-C}_{12}\text{H}_{26}$), alkyl benzenes, and naphthalene and its derivatives. Kerosene is less volatile than gasoline; it boils between about 140°C (285°F) and 320°C (610°F).

Kerosene is intermediate in volatility between gasoline and gas/diesel oil. It is a medium oil distilling between 150 and 300°C (300 to 570°F). Kerosene has a flash point about 25°C (77°F) and is suitable for use as an illuminant when burned in a wide lamp. The term *kerosene* is also too often incorrectly applied to various fuel oils, but a fuel oil is actually any liquid or liquid petroleum product that produces heat when burned in a suitable container or that produces power when burned in an engine.

Kerosene, because of its use as a burning oil, must be free of aromatic and unsaturated hydrocarbons, as well as free of the more obnoxious sulfur compounds. The desirable constituents of kerosene are saturated hydrocarbons, and it is for this reason that kerosene is manufactured as a straight-run fraction, not by a cracking process.

Manufacture

Kerosene was first manufactured in the 1850s from coal tar, and the name coal oil is often applied to kerosene, but petroleum became the major source after 1859. From that time, the kerosene fraction is, and has remained, a distillation fraction of petroleum. However, the quantity and quality vary with the type of crude oil, and although some crude oils yield excellent kerosene quite simply, others produce kerosene that requires substantial refining.

Kerosene is now largely produced by cracking the less volatile portion of crude oil at atmospheric pressure and elevated temperatures. In the early days of kerosene production, the poorer-quality kerosene was treated with large quantities of sulfuric acid to convert them to marketable products. However, this treatment resulted in high acid and kerosene losses, but the later development of the *Edeleanu* process overcame these problems.

Kerosene is a very stable product, and additives are not required to improve the quality. Apart from the removal of excessive quantities of aromatics by the *Edeleanu* process, kerosene fractions may need only a lye wash or a doctor treatment if hydrogen sulfide is present to remove mercaptans.

Properties and Use

Kerosene is by nature a fraction distilled from petroleum that has been used as a fuel oil from the beginning of the petroleum-refining industry. As such, low proportions of aromatic and unsaturated hydrocarbons are desirable to maintain the lowest possible level of smoke during burning. Although some aromatics may occur within the boiling range assigned to kerosene, excessive amounts can be removed by extraction; that kerosene is not usually prepared from cracked products almost certainly excludes the presence of unsaturated hydrocarbons.

The essential properties of kerosene are flash point, fire point, distillation range, burning, sulfur content, color, and cloud point. In the case of the flash point (ASTM D56), the minimum flash temperature is generally placed above the prevailing ambient temperature; the fire point (ASTM D92) determines the fire hazard associated with its handling and use.

The boiling range (ASTM D86) is of less importance for kerosene than for gasoline, but it can be taken as an indication of the viscosity of the product, for which there is no requirement for kerosene. The ability of kerosene to burn steadily and cleanly over an extended period (ASTM D187) is an important property and gives some indication of the purity or composition of the product.

The significance of the total sulfur content of a fuel oil varies greatly with the type of oil and the use to which it is put. Sulfur content is of great importance when the oil to be burned produces sulfur oxides that contaminate the surroundings. The color of kerosene is of little significance, but a product darker than usual may have resulted from contamination or aging, and in fact a color darker than specified (ASTM D156) may be considered by some users as unsatisfactory. Finally, the cloud point of kerosene (ASTM D2500) gives an indication of the temperature at which the wick may become coated with wax particles, thus lowering the burning qualities of the oil.

Kinematic Viscosity

The kinematic viscosity of a liquid is the ratio of viscosity to density, both measured at the same temperature and can be obtained by dividing the absolute viscosity of a fluid with the mass density of the fluid:

$$\nu = \mu/\rho$$

ν is the kinematic viscosity, μ is the absolute or dynamic viscosity, and ρ is the density.

In the SI-system, the theoretical unit is m^2/s or commonly used Stoke (St)

$$1 \text{ St} = 10^{-4} \text{ m}^2/\text{s}$$

The Stoke is an impractical large unit; it is usually divided by 100 to give the unit called Centistokes (cSt):

$$1 \text{ St} = 100 \text{ cSt}$$

$$1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{s}$$

Since the specific gravity of water at 20.2°C (68.4°F) is almost unity, the kinematic viscosity of water at 20.2°C (68.4°F) is 1.0 cSt.

The viscosity of a fluid is highly temperature dependent, and for either dynamic or kinematic viscosity to be meaningful, the reference temperature must be quoted. The usual reference temperature for a residual fluid is 100°C (212°F), and for a distillate fluid, the usual reference temperature is 40°C (104°F). For a liquid, the kinematic viscosity will decrease with an increase in temperature, but for a gas, the kinematic viscosity will increase with increase in temperature.

Saybolt Universal Seconds (SUS) is used to measure viscosity. The efflux time is Saybolt Universal Seconds (SUS) required for 60 milliliters of a petroleum product to flow through the calibrated orifice of a Saybolt Universal

viscometer, under carefully controlled temperature (ASTM D88). This method has largely been replaced by the kinematic viscosity method.

Kinematic viscosity versus dynamic or absolute viscosity can be expressed as:

$$\nu = 4.63\mu/(\text{specific gravity})$$

ν is the kinematic viscosity (SSU), μ is the dynamic or absolute viscosity (cP), and SG is the specific gravity.

Koppers-Totzek Gasifier

The Koppers-Totzek gasifier is a commercially established, high-temperature, entrained flow gasifier capable of partially oxidizing a wide variety of feed stocks at pressures slightly above atmospheric.

Biomass gasification is an old technology that is viewed as an alternative to conventional fuel. In the gasification process, wood, charcoal, and other biomass materials are gasified to produce the so-called 'producer gas' for power or electricity generation. Gasification system basically consists of a gasifier unit, purification system, and energy converters – burner or engine.

A wide range of biomass fuels such as wood, charcoal, wood waste (branches, roots, bark, saw dust) as well as agricultural residues – maize cobs, coconut shells, cereal straws, and rice husks – can be used as fuel for biomass gasification. Theoretically, almost all kinds of biomass with moisture content of 5 to 30% can be gasified; however, not every biomass fuel leads to successful gasification.

The gasifier has two-headed burner, has heads 180° apart, and is about 24 feet high and has an inside diameter of up to 3.5 m. A four-headed gasifier, with burners 90° apart. The burner heads are opposed to ensure that particles escaping from one burner will be burnt in the opposite burner. Carbon is oxidized in the gasifier producing a high-temperature flame zone of about 1,900°C (3,450°F). Heat losses and the endothermic carbon-steam reactions reduce the exit temperature to around 1,500°C (2,730°F). The feedstock is gasified nearly to completion in times or the order of 1 second. Carbon conversion, dependent on the reactivity of the feedstock, is about 96 to 98%. At the prevailing high operating temperatures, gaseous and vaporous hydrocarbons emanating from the feedstock decompose so rapidly that coagulation of feedstock particles during the plastic stage does not occur. Thus, any feedstock can be gasified regardless of its caking property, ash content, or ash fusion temperature.

Also, only gaseous products are produced; no tars, condensable hydrocarbons, or phenols are formed. Approximately 50% of the mineral matter drops out as slag. The remainder of the ash leaves the gasifier as fine slag particles entrained in the exit gas. Gas leaving the gasifier may be directly water quenched to solidify entrained slag droplets, if necessary, before passing through a waste heat boiler where high pressure steam is produced. The gas exits the waste heat boiler at 175 to 260°C (340 to 500°F).

The gasifier is, in many ways, similar to the Texaco gasifier. The feedstock is dried, pulverized, and conveyed with nitrogen from storage to the gasifier service bin and feed bins. Variable-speed feedstock screw feeders then continuously discharge the feedstock into a mixing nozzle, where a mixture of steam and oxygen entrains the pulverized feedstock. Moderate temperature and high burner velocity prevent oxidation of the feedstock.

Koppers-Totzek Gasifier – Biomass Gasification

Biomass gasification is an old technology that is viewed as an alternative to conventional fuel. In the gasification process, wood, charcoal, and other biomass materials are gasified to produce the so-called 'producer gas' for power or electricity generation. Gasification system basically consists of a gasifier unit, purification system, and energy converters – burner or engine.

A wide range of biomass fuels such as wood, charcoal, wood waste (branches, roots, bark, saw dust) as well as agricultural residues – maize cobs, coconut shells, cereal straws, and rice husks – can be used as fuel for biomass

gasification. Theoretically, almost all kinds of biomass with a moisture content of 5 to 30% can be gasified; however, not every biomass fuel leads to successful gasification.

The gasifier is a refractory-lined steel shell (equipped with a steam jacket for producing low-pressure process steam) that is commonly used to process coal. A two-headed burner has heads 180° apart, and the gasifier is about 24 feet high and has an inside diameter of up to 3.5 m. The burner heads are opposed to ensure that particles escaping from one burner will be burnt in the opposite burner. Carbon is oxidized in the gasifier producing a high temperature flame zone of approximately 1,900°C (3,450°F). Heat losses and the endothermic carbon-steam reactions reduce the exit temperature to around 1,500°C (2,730°F).

The feedstock is gasified nearly to completion in times or the order of 1 second. Carbon conversion, dependent on the reactivity of the feedstock, is about 96 to 98%. At the prevailing high operating temperatures, gaseous and vaporous hydrocarbons emanating from the feedstock decompose so rapidly that coagulation of feedstock particles during the plastic stage does not occur. Thus any feedstock can be gasified regardless of its caking property, ash content, or ash fusion temperature.

Also, only gaseous products are produced; no tars, condensable hydrocarbons, or phenols are formed. Approximately 50% of the feedstock ash drops out as slag. The remainder of the ash leaves the gasifier as fine slag particles entrained in the exit gas. Gas leaving the gasifier may be directly water-quenched to solidify entrained slag droplets, if necessary, before passing through a waste heat boiler where high pressure steam is produced. The gas exits the waste heat boiler at 175 to 260°C (345 to 500°F).

The gasifier is, in many ways, similar to the Texaco gasifier. The feedstock is dried, pulverized, and conveyed with nitrogen from storage to the gasifier service bin and feed bins. Variable-speed feedstock screw feeders then continuously discharge the feedstock into a mixing nozzle, where a mixture of steam and oxygen entrains the pulverized feedstock. Moderate temperature and high burner velocity prevent oxidation of the feedstock.

Koppers-Totzek Process

The Koppers-Totzek process is, perhaps the best known of the entrained-solids processes and operates at atmospheric pressure. The reactor is a relatively small, cylindrical, refractory-lined vessel into which feedstock, oxygen, and steam are charged. The reactor typically operates at an exit temperature of about 1,480°C (2,700°F), and the pressure is maintained slightly above atmospheric pressure.

Gases and vaporized hydrocarbons produced by the feedstock at medium temperatures immediately pass through a zone of high temperature in which they decompose so rapidly that feedstock particles in the plastic stage do not agglomerate, and thus any type of feedstock can be gasified irrespective of caking tendencies, ash content, or ash fusion temperature. The gas product contains no ammonia, tars, phenols, or condensable and can be upgraded to synthesis gas by reacting all or part of the carbon monoxide content with steam to produce additional hydrogen plus carbon dioxide.

The Koppers-Totzek process is an entrained-solids process which operates at atmospheric pressure. The reactor is a cylindrical, refractory-lined feedstock burner into which feedstock, oxygen, and steam are charged through at least two burner heads.

The feed feedstock for the process is crushed (so that 70% will pass through a 200-mesh screen), mixed with oxygen and low-pressure steam, and injected into the gasifier through a burner head. The heads are spaced 180 or 90° apart (representing two-headed or four-headed opposed burner arrangements) and are designed such that steam envelopes the flame and protects the reactor walls from excessive heat.

The reactor typically operates at an exit temperature of approximately 1,480°C (2,700°F), and the pressure is maintained just slightly above atmospheric. Only about 85 to 90% of the total carbon may be gasified in a single pass through the gasifier because carbon conversion is a function of the reactivity of the feedstock and approaches 100% for lignite.

The heat in the reactor causes the formation of slag from mineral ash, and this is removed from the bottom of the gasifier through a water seal. Gases and vaporized hydrocarbons produced by the feedstock at medium temperatures immediately pass through a zone of high temperature in which they decompose so rapidly that feedstock particles in

the plastic stage do not agglomerate, and thus any type of feedstock can be gasified irrespective of caking tendencies, ash content, or ash fusion temperature.

In addition, the high operating temperature ensures that the gas product contains no ammonia, tars, phenols, or condensable hydrocarbons. The raw gas can be upgraded to synthesis gas by reacting all or part of the carbon monoxide content with steam to produce additional hydrogen plus carbon dioxide.

Kopp's Law

Kopp's law refers to either of two relationships which are (i) the molecular heat capacity of a solid compound which is the sum of the atomic heat capacities of the elements composing it, and (ii) the elements having atomic heat capacities lower than those required by the law of Dulong and Petit retain these lower values in their compounds. Also, there is a regular relationship between boiling points and the number of methylene (CH_2) groups present in the molecule.

Kraft Process

The Kraft chemical recovery process is a mature, effective technology that provides for recycling of the pulping chemicals, efficient generation of steam and electrical power from the fuel value of the black liquor, and effective disposal of dissolved wood substances. Thus:

Wood (lignin + fiber)	white liquor ($\text{NaOH} + \text{Na}_2\text{S}$)	black liquor (+ fiber)
--------------------------	---	---------------------------

In the process, which uses sodium hydroxide (NaOH) and sodium sulfide (Na_2S) to pulp wood, approximately 50% w/w of the wood is dissolved, and together with the spent pulping chemicals, forms a liquid stream called weak black liquor. The weak black liquor is separated from the pulp by washing, and is sent to the recovery system, where the inorganic pulping chemicals are recovered for reuse, while the dissolved organics are used as a fuel to make steam and power.

The process has three main functions, which are (i) to minimize the environmental impact of waste material – the black liquor – from the pulping process, (ii) recycling the pulping chemicals, sodium hydroxide and sodium sulfide, NaOH and Na_2S ; and (iii) co-generating steam and power.

Landfill Classification

A landfill site is an area of land that has been specifically engineered to allow for the deposition of waste on to and into it. Municipal solid waste landfill sites are a large source of human-related methane *emissions* and, in some countries such as the United States, can account for up to 25% of these emissions. At the same time, methane emissions from landfills represent a lost opportunity to capture and use a significant energy resource.

Historically, a landfill has been called a dump or a midden and has been the most convenient method of waste disposal for millennia. Landfills may include internal waste disposal sites (where a producer of waste carries out their own waste disposal at the place of production) as well as sites used by many producers. Many landfills are also used for other waste management purposes, such as the temporary storage, consolidation and transfer, or processing of waste material (sorting, treatment, or recycling). A landfill also may refer to ground that has been filled in with soil and rocks instead of waste materials, so that it can be used for a specific purpose, such as for building houses.

Landfill sites are classified according to the type(s) of waste material contained therein, viz: (i) hazardous waste landfill site, (ii) sanitary landfill site, (iii) inert waste landfill site, and (iv) dump site (Table L-1). In the hazardous waste landfill site, waste disposal units are constructed to specific design criteria and which receive wastes meeting the local definition of hazardous waste. These landfills are generally constructed to be secure repositories for material that presents a serious hazard to human health, such as high-level radioactive waste. They are restricted, by permit or law, to the types of waste that they may handle (chemical vs. radioactive, liquid vs. dry). Double liner systems are the norm for hazardous waste landfills.

Table L-1 General classification of landfill sites.

Landfill type	Description
Dump	Also simply referred to as a landfill.
	Not engineered with the special protective measures required by sanitary landfills.
	Most common in rural, remote, and developing areas.
	Many jurisdictions prohibit the use of non-sanitary landfills for the disposal of municipal solid waste.
	Some jurisdictions that do allow dumps may require them to be constructed according to some engineering standard to mitigate the risk for environmental contamination, such as by limiting the slope, requiring compaction, or ensuring that the cell is high enough above the groundwater table.
Vegetation waste	Also known as yard waste and stump fill areas.
	Used to dispose of vegetation wastes.
	Generally unregulated prior to the 1980s.
	In areas where burning was prohibited, these areas were used by land developers to bury trees and brush cleared from land used for subdivisions and commercial developments.
Animal waste	An area where massive amounts of manure and, possibly, animal carcasses are disposed.
	As a result of the high organic content, methane production can be significant.

(Continued)

Table L-1 General classification of landfill sites. (*Continued*)

Landfill type	Description
	Decaying manure and carcasses will produce strong odors.
	Fires have occurred on some animal waste landfills, increasing health and safety concerns.
Inert waste	A waste disposal unit that receives wastes which are chemically and physically stable and do not undergo decomposition, such as sand, bricks, concrete, and gravel.
Sanitary	Normally refers to those where municipal solid waste is disposed of, as well as other wastes high in organic material
	Also called modern, engineered, or secure landfills.
	Usually have physical barriers such as liners and leachate collection systems, and procedures to protect the public from exposure to the disposed wastes. The term sanitary landfill.
Hazardous waste	Waste disposal units constructed to specific design criteria and which receive wastes meeting the local definition of hazardous waste.
	Generally constructed to be secure repositories for material that presents a serious hazard to human health, such as high-level radioactive waste.
	Restricted, by permit or law, to the types of waste that they may handle (chemical vs. radioactive, liquid vs. dry).
	Double liner systems are the norm for hazardous waste landfills.

A sanitary landfill site (also called modern, engineered, or secure landfills) usually has physical barriers such as liners and leachate collection systems, and procedures to protect the public from exposure to the disposed wastes. The term sanitary landfill normally refers to those where municipal solid waste is disposed of, as well as other wastes high in organic material. In some countries, all landfills are sanitary landfills.

The inert waste landfill site waste is used for receiving wastes which are chemically and physically stable and do not undergo decomposition, such as sand, bricks, concrete, or gravel.

The dump site: also simply called landfills; dumps are landfills that are not engineered with the special protective measures required by sanitary landfills. They are most common in rural, remote, and developing areas. Many jurisdictions prohibit the use of non-sanitary landfills for the disposal of municipal solid waste. Other jurisdictions that do allow dumps may require them to be constructed according to some engineering standard to mitigate the risk for environmental contamination, such as by limiting the slope, requiring compaction, or ensuring that the cell is high enough above the groundwater table.

Whatever the classification, the landfill site should be designed in such fashion that there is minimal harm to the environment and that the land may be restored in some way after the period of waste disposal. Despite its connotations as an out of sight, out of mind solution, landfill is a well-used method of waste management that is applied to the majority of solid wastes in many countries and can be used as a source for biogas.

The production of alternate fuels from landfill gas is an emerging area. Landfill gas has been successfully delivered to the natural gas pipeline system as both a high-Btu and medium-Btu fuel. Landfill gas has also been converted to vehicle fuel in the form of compressed natural gas (CNG), with a number of liquefied natural gas (LNG), and can also be used for methanol production.

Most modern landfill sites are engineered to contain liquid leachate or landfill gas produced by decomposing organic waste, even to the point of requiring a minimum of one landfill liner. This consists of a layer of compacted clay with a minimum required thickness and a maximum allowable hydraulic conductivity. A deep geological repository of high-level radioactive waste is not generally classified as a landfill site.

Municipal solid waste contains significant portions of organic materials that produce a variety of gaseous products when dumped, compacted, and covered in landfills. Anaerobic bacteria thrive in the oxygen-free environment, resulting in the decomposition of the organic materials and the production of primarily carbon dioxide and methane.

Carbon dioxide is likely to leach out of the landfill because it is soluble in water. Methane, on the other hand, which is less soluble in water and lighter than air, is likely to migrate out of the landfill. Landfill gas energy facilities capture the methane (the principal component of natural gas) and combust it for energy.

However, not all landfills are capable of producing landfill gas that is usable as an energy gas. Gas production is dependent upon the composition of the waste in the landfill, and this, in turn, dictates the classification of the landfill.

See also: Biogas, Landfill Gas, Waste, Waste-To-Energy.

Landfill Gas

Landfill gas (LFG, sometimes referred to under the collective groups known as biogas) is not the same as natural gas or methane; each has a separate identity, and the names should not be used interchangeably. Landfill gas is produced by the microbial decomposition of landfilled waste in an oxygen-free (anaerobic) atmosphere. This generally occurs under semi-controlled conditions in a landfill; its constituents depend on the composition and age of the waste.

Landfill gas is, in fact, a fuel gas that is a by-product of current landfilling practices and hence occurs only after municipal solid waste has been sent for disposal to a landfill site. The anaerobic digestion of the buried solid organic waste produces the landfill gas naturally, as the bacterial decomposition of the organic matter continues over time. In the long run, as the use of landfills necessarily dwindle, landfill gas will disappear as a resource. It is thus of an inherently transient nature, but will be covered here as many examples of landfill gas plants exist.

The term landfill methane is deceiving as it may seem to imply (incorrectly) that landfill gas is simply methane. Landfill gas is produced by the microbial decomposition of landfilled waste in an oxygen-free (anaerobic) atmosphere. The gas is approximately 65% v/v methane and 35% v/v carbon dioxide as well as traces of other constituents (Table L-2), but the composition of the gas does vary with age and the type of waste. The odor of landfill gas is associated with trace compounds such as hydrogen sulfide, mercaptans, and ethylene. On occasion, mercury and even radioactive contaminants such as tritium (radioactive hydrogen) have been found in landfill gas.

Table L-2 Typical constituents of landfill gas.*

Component	% v/v	Characteristics
Ammonia	0.1-1	Colorless gas with a pungent odor.
Carbon dioxide	40-60	Colorless, odorless, and slightly acidic.
Carbon monoxide	0.0-2	Colorless, odorless.
Hydrogen	0-0.2	Colorless, odorless, tasteless.
Methane	45-60	A naturally occurring gas; colorless and odorless.
Nitrogen	2-5	Colorless, odorless, and tasteless.
NMOCs**	0.01-0.6	Organic compounds excluding methane.
Oxygen	0.1-1	Colorless, odorless, tasteless.
Sulfides	0-1	Hydrogen sulfide, dimethyl sulfide, mercaptans

*Listed alphabetically rather than by occurrence.

**Non-methane organic compounds.

The rate and duration of gas production depends on the nature of the waste and oxygen availability. Some sites may continue gassing for over 50 years. The gas can move or migrate in any direction within the site, depending on the permeability of the waste layers. It can also migrate off-site if measures are not taken to prevent it. One indication that gas is escaping from the site and venting through the ground outside is the presence of yellow and dying vegetation.

The length of time and amount of gas that is available from a landfill site is specific to the type of waste, moisture content, temperature, acidity, and the design of the site. As the diagram above shows, gas is drawn up from vertical or horizontal wells through a system of pipes. At this stage, the gas is usually warm and saturated with moisture.

The extraction pipes contain condensate traps and are laid at an angle so that as the gas cools, the moisture does not hinder the flow of the gas. The condition of the gas is specific to what use it will be put to.

The rate and duration of gas production depends on the nature of the waste and oxygen availability. The gas can move or migrate in any direction within the site, depending on the permeability of the waste layers. It can also migrate off-site if measures are not taken to prevent it. One indication that gas is escaping from the site and venting through the ground outside is the presence of yellow and dying vegetation.

A main concern with landfill gas is the possibility of gas accumulation inside buildings constructed on or close to a landfill site. Protection of new buildings is usually achieved using a dual barrier approach: low permeability gas membrane to resist the passage of gas, and some form of ventilation/extraction system to disperse the gas safely to the atmosphere. The requirements for particular developments will be specified by the relevant planning authorities. Gas monitoring may also be a requirement and, if so, indicates that gas detectors must be installed at the most effective location.

Gas monitoring and control measures are the responsibility of the site operator, and the aim of gas control is to prevent migration off-site. This can be achieved by a gas barrier (lining of the excavation) combined with stone-filled vent trenches which can vent gas to atmosphere. Venting can also be carried out using borehole pipes spread throughout the site or at selected points where gas can be pumped to them through a gas drainage system inside the tip. If the quantity or quality (odor) of the gas is such that it requires destroying, a flare system may be adopted. Landfill gas can also be exploited for industrial use as fuel for heat or to produce electricity.

Collection

In order to use the landfill gas, it must first be collected from the landfill. A collection system usually consisting of vertical extraction wells gas pipeline, blower units, and possibly a flare to burn off gases safely is used. These collection wells are placed strategically throughout the landfill site. If the gas production is significant, each extraction well is connected to the main gas line, which carries the gas to a station; landfill operators can either sell the gas or use it for energy.

The gas is extracted from the landfill by means of a gas pump or a compressor leading the gas to a utilization plant by means of pressure in the transmission pipe. The connection of the single wells to the pump and utilization system can be done in different ways. The most common method, is to connect the wells to a main collection pipe which goes around on the landfill. The main problem with this system is the difficulty involved with the regulation of both the quality and quantity of the gas. Another problem is to find the location of leakiness when all the wells are connected in one big system. To save operation costs and to have good conditions for the workers, the best solution is to have single pipes from each well to a pump and regulation house.

Composition

The composition of landfill gas is variable (Table L-2), and the evolution rate of the gas from the landfill and the quantity of gas are dependent on a number of factors. These factors include (i) the composition of the waste, (ii) the age of waste, (iii) the presence of oxygen, (iv) the moisture content of the waste, (v) the temperature, (vi) the input rate of the waste, (vii) the ambient pH, (viii) the density of the waste density which is an indicator of whether is waste is tightly packed or loosely packed), and (ix) the management strategy/strategies of the site.

The composition of the waste, especially the amount of organic waste present in a landfill, determines the level of bacterial activity and the degree of bacterial decomposition. Some types of organic waste contain nutrients, such as sodium, potassium, calcium, and magnesium, which help bacteria thrive. When these nutrients are present, landfill gas production increases. Alternatively, some wastes contain compounds that harm bacteria, causing less gas to be produced. For example, methane-producing bacteria can be inhibited when waste has high salt concentrations.

The presence of oxygen in a landfill also dictates the mode of decomposing. Only when oxygen is used up will bacteria begin to produce methane. The more oxygen present in a landfill, the longer aerobic bacteria can decompose waste during the first phase of the decomposition. If waste is loosely buried or frequently disturbed, more oxygen is available, so that oxygen-dependent bacteria live longer and produce carbon dioxide and water for longer periods. If the waste is highly compacted, however, methane production will begin earlier as the aerobic bacteria are replaced by

methane-producing anaerobic bacteria in the third phase of the decomposition. Methane gas starts to be produced by the anaerobic bacteria only when the oxygen in the landfill is used up by the aerobic bacteria; therefore, any oxygen remaining in the landfill will slow methane production. Barometric highs will tend to introduce atmospheric oxygen into surface soils in shallow portions of a landfill, possibly altering bacterial activity. In this scenario, waste in the fourth phase of the decomposition, for example, might briefly revert to Phase I until all the oxygen is used up again.

The presence of water in a landfill increases gas production because moisture encourages bacterial growth and transports nutrients and bacteria to all areas within a landfill. A moisture content of 40% or higher, based on wet weight of waste, promotes maximum gas production (e.g., in a capped landfill). Waste compaction slows gas production because it increases the density of the landfill contents, decreasing the rate at which water can infiltrate the waste. The rate of gas production is higher if heavy rainfall and/or permeable landfill covers introduce additional water into a landfill.

Temperature effects can vary, but, generally, warm temperatures increase bacterial activity, which in turn increases the rate of landfill gas production. Colder temperatures inhibit bacterial activity. Typically, bacterial activity drops off dramatically below 10°C (50°F). Weather changes have a far greater effect on gas production in shallow landfills because the bacteria are not as insulated against temperature changes as compared to deep landfills where a thick layer of soil covers the waste. A capped landfill usually maintains a stable temperature, maximizing gas production. Bacterial activity releases heat, stabilizing the temperature of a landfill between 77°F and 113°F, although temperatures up to 158°F have been noted. Temperature increases also promote volatilization and chemical reactions. As a general rule, emissions of organic compounds other than methane double with every 10°C (18°F) increase in temperature.

The age of refuse is also an important factor – recently buried waste will produce more gas than older waste. Landfills usually produce appreciable amounts of gas within 1 to 3 years. Peak gas production usually occurs 5 to 7 years after wastes are dumped. Almost all gas is produced within 20 years after waste is dumped; however, small quantities of gas may continue to be emitted from a landfill for 50 or more years. A low-methane yield scenario, however, estimates that slowly decomposing waste will produce methane after 5 years and continue emitting gas over a 40-year period. Different portions of the landfill might be in different phases of the decomposition process at the same time, depending on when the waste was originally placed in each area. The amount of organic material in the waste is an important factor in how long gas production lasts.

In addition, the pressure of the gas is also affected by (i) the rate of landfill gas evolution since a higher rate of gas evolution will result in an increase in the pressure of the landfill, (ii) the permeability of the surrounding waste types and or strata (rock type) since more permeable waste and or rock types will result in lower pressures as they will allow the landfill gas to migrate further than less permeable types, and (iii) variations in leachate levels since an increase in leachate levels lead to a decrease in volume and thus the pressure within the landfill increases.

Extraction

Landfill gas is extracted from landfills using a series of wells and, if necessary, a blower/flare (or vacuum) system.

The recovery system is constructed so that there is no leak of gas to the surrounding land or air. This methane and carbon dioxide mixture can be used in the same combustion process discussed previously. The generation equipment is usually contained within the same area as the extraction plant. This site is usually away from urban sites due to safety reasons and amenity.

This system directs the collected gas to a central point where it can be processed and treated depending upon the ultimate use for the gas. From this point, the gas can be simply flared or used to generate electricity, replace fossil fuels in industrial and manufacturing operations, fuel greenhouse operations, or be upgraded to pipeline quality gas.

A landfill gas extraction facility will typically consist of gas well fields, a gas processing plant, and a gas delivery pipeline to the customer. This will allow (i) recovery of the crude gas being generated within the landfill, (ii) the ability to process the gas to produce medium Btu gas – approximately 500 Btu/ft³, and (iii) delivery to a pipeline of specification gas.

At the facility, the gas is drawn from the wells and sent to a main collection header and thence to the processing plant. Vapor-liquid separators are used to separate water and any liquid condensate from the gas. The condensate is

usually a mixture of hydrocarbon derivatives that resembles contaminated gasoline or kerosene. Further vapor contaminant removal is accomplished by solvent scrubbing. The crude gas is compressed and then cooled and scrubbed by countercurrent solvent flow.

Formation

Most landfill gas is produced by bacterial decomposition, which occurs when organic waste is broken down by bacteria naturally present in the waste and in the soil used to cover the landfill. Organic wastes include food, garden waste, street sweepings, textiles, and wood and paper products.

Bacteria decompose organic waste in four phases, and the composition of the gas changes during each phase. Bacteria decompose landfill waste in four phases. The composition of the gas produced changes with each of the four phases of decomposition. Landfills often accept waste over a 20- to 30-year period, so waste in a landfill may be undergoing several phases of decomposition at once. This means that older waste in one area might be in a different phase of decomposition than more recently buried waste in another area.

During the first phase of decomposition, aerobic bacteria consume oxygen while breaking down the long molecular chains of complex carbohydrates, proteins, and lipids that comprise organic waste. The primary by-product of this process is carbon dioxide. Nitrogen content is high at the beginning of this phase, but declines as the landfill moves through the four phases. The chemistry of this first phase continues until the available oxygen is depleted. This phase can last for days or months, depending on how much oxygen is present when the waste is disposed in the landfill. Oxygen levels will vary according to factors such as how loose or compressed the waste was when it was buried.

The second phase of Phase II decomposition starts after the oxygen in the landfill has been used up. Using an anaerobic process (a process that does not require oxygen), bacteria convert compounds created by aerobic bacteria into acetic, lactic, and formic acids and alcohols such as methanol and ethanol. The landfill becomes highly acidic. As the acids mix with the moisture present in the landfill, they cause certain nutrients to dissolve, making nitrogen and phosphorus available to the increasingly diverse species of bacteria in the landfill. The gaseous by-products of these processes are carbon dioxide and hydrogen. If the landfill is disturbed or if oxygen is somehow introduced into the landfill, microbial processes will return to the first phase.

The third phase of decomposition starts when certain kinds of anaerobic bacteria consume the organic acids produced in second phase and form acetate, an organic acid. This process causes the landfill to become a more neutral environment in which methane-producing bacteria begin to establish themselves. Methane- and acid-producing bacteria have a symbiotic, or mutually beneficial, relationship. Acid-producing bacteria create compounds for the methanogenic bacteria to consume. Methanogenic bacteria consume the carbon dioxide and acetate, too much of which would be toxic to the acid-producing bacteria.

The final phases of the decomposition begin when both the composition and production rates of landfill gas remain relatively constant. At this stage, the landfill gas usually contains approximately 45% to 60% methane by volume, 40% to 60% carbon dioxide, and 2% to 9% other gases, such as sulfides. Gas is produced at a stable rate during this final phase – typically for approximately 20 years. However, gas will continue to be emitted for 50 or more years after the waste is placed in the landfill. Gas production might last longer, for example, if greater amounts of organics are present in the waste, such as at a landfill receiving higher than average amounts of domestic animal waste.

Several factors affect the composition of landfill gas, and these are (i) composition of the waste, (ii) oxygen in the landfill, (iii) moisture content of the waste/landfill, (iv) temperature, and (v) time of burial of the waste in the landfill.

In terms of waste composition, the more organic waste present in a landfill, the more landfill gas is produced by bacterial decomposition. Some types of organic waste contain nutrients, such as sodium, potassium, calcium, and magnesium, which help bacteria thrive. When these nutrients are present, landfill gas production increases. Alternatively, some wastes contain compounds that harm bacteria, causing less gas to be produced. For example, methane-producing bacteria can be inhibited when waste has high salt concentrations.

Only when oxygen is used up will bacteria begin to produce methane. The more oxygen present in a landfill, the longer aerobic bacteria can decompose waste in Phase I. If waste is loosely buried or frequently disturbed, more oxygen is available, so that oxygen-dependent bacteria live longer and produce carbon dioxide and water for longer periods. If the waste is highly compacted, however, methane production will begin earlier as the aerobic bacteria are replaced by methane-producing anaerobic bacteria in Phase III. Methane gas starts to be produced by the anaerobic bacteria only when the oxygen in the landfill is used up by the aerobic bacteria; therefore, any oxygen remaining in

the landfill will slow methane production. Barometric highs will tend to introduce atmospheric oxygen into surface soils in shallow portions of a landfill, possibly altering bacterial activity. In this scenario, waste in Phase IV, for example, might briefly revert to Phase I until all the oxygen is used up again.

The presence of water in a landfill increases gas production because moisture encourages bacterial growth and transports nutrients and bacteria to all areas within a landfill. A moisture content of 40% or higher, based on wet weight of waste, promotes maximum gas production (e.g., in a capped landfill). Waste compaction slows gas production because it increases the density of the landfill contents, decreasing the rate at which water can infiltrate the waste. The rate of gas production is higher if heavy rainfall and/or permeable landfill covers introduce additional water into a landfill.

A slightly elevated temperature increases bacterial activity, which in turn increases the rate of landfill gas production. Colder temperatures inhibit bacterial activity. Typically, bacterial activity drops off dramatically below 10°C (50°F). Weather changes have a far greater effect on gas production in shallow landfills. This is because the bacteria are not as insulated against temperature changes as compared to deep landfills where a thick layer of soil covers the waste. A capped landfill usually maintains a stable temperature, maximizing gas production. Bacterial activity releases heat, stabilizing the temperature of a landfill between 25 and 45°C (77 and 113°F), although temperatures up to 70°C (158°F) have been noted. Temperature increases also promote volatilization and chemical reactions. As a general rule, emissions of the non-methane organic compounds double with every 10°C (18°F) increase in temperature.

The time of burial is also a factor in gas production – for example, waste that has recently been buried will produce more gas than older waste. Landfills usually produce appreciable amounts of gas within 1 to 3 years. Peak gas production usually occurs 5 to 7 years after wastes are dumped. Almost all gas is produced within 20 years after waste is dumped; however, small quantities of gas may continue to be emitted from a landfill for 50 or more years. A low-methane yield scenario, however, estimates that slowly decomposing waste will produce methane after 5 years and continue emitting gas over a 40-year period. Different portions of the landfill might be in different phases of the decomposition process at the same time, depending on when the waste was originally placed in each area. The amount of organic material in the waste is an important factor in how long gas production lasts.

There are five major reaction processes involved with different microorganisms involved at each stage and, although much more complex, the chemistry occurring at landfill sites is generally represented in the simplest form as the decomposition of cellulose and hemicellulose.

For cellulose:

For hemicellulose:

The reactions actually occur in stages, and cellulose and hemicellulose are not the only starting materials.

The initial stage of organic decomposition occurs during the placement of the waste in the landfill and for the period of time after, when oxygen is available within the waste. There, chemical processes are initiated and facilitated by the presence of aerobic micro-biota which metabolize a fraction of the organic waste to produce simpler hydrocarbon derivatives, water, carbon dioxide, and, as this is an exothermic reaction, heat (the heat generated can raise the temperature of the waste to up to 70 to 90°C (160 to 195°F); however, compacted waste achieves lower temperatures due to the reduced availability of oxygen).

In these reactions, water and carbon dioxide are produced in the greatest concentrations. The carbon dioxide can dissolve in the water, forming a leachate that is rich in carbonic acid, which, in turn, lowers the pH of the surroundings. This stage generally lasts for a matter of days or weeks, depending on the amount of oxygen that is available within the waste.

The removal of oxygen during the hydrolysis and aerobic degradation facilitates a change in conditions from aerobic (oxygen present) to anaerobic (oxygen absent). Thus the majority of microbiota found within the waste change to anaerobic species. Carbohydrates are hydrolyzed (a chemical process in which a molecule is split into two parts

by the addition of a water molecule) to sugars, which are then further decomposed to form carbon dioxide, hydrogen, ammonia, and organic acids. Proteins decompose via removal of an amino (NH_2) group to form ammonia, carboxylic acids, and carbon dioxide. The leachate that is produced at this stage contains ammoniacal nitrogen in high concentration. Acetic acid is the main organic acid formed, but propionic, butyric, lactic and formic acids, and acid derivative products are also produced, and their formation is affected by the composition of the initial waste material. The temperatures in the landfill drop to between 30 and 50°C (86 and 122°F). Gas composition may rise to levels of up to 80% carbon dioxide and 20% hydrogen.

In the acetogenesis stage, anaerobic conditions are still present and the organic acids that were formed in the hydrolysis and fermentation stage are now converted, via specific microorganisms to acetic acid, acetic acid derivatives, carbon dioxide, and hydrogen. Other microorganisms convert carbohydrates directly to acetic acid in the presence of carbon dioxide and nitrogen. Hydrogen and carbon dioxide levels begin to diminish toward the end of this stage, with the lower hydrogen concentrations promoting the methane-generating microorganisms (methanogens), which subsequently generate methane and carbon dioxide from the organic acids and their derivatives generated in the earlier stages.

The methanogenesis stage encompasses the main processes that lead to the production of landfill gas. At this point, the chemical processes involved are comparatively slow and can take many years to complete. Oxygen-depleted, anaerobic conditions still remain as in the previous two stages. Low levels of hydrogen are required to promote the methanogenic organisms, which generate carbon dioxide and methane from the organic acids and their derivatives such as acetate derivatives and formate derivatives that are formed in the earlier stages. Methane generation may also occur from the direct conversion of hydrogen and carbon dioxide (via microorganisms) in to methane and water: Hydrogen concentrations, produced during Stages 2 and 3, therefore fall to low levels during this fourth stage.

Oxidation processes mark the final stage of the reactions involved in the biodegradation of waste. As the acids are used up in the production of landfill gas, new aerobic microorganisms slowly replace the anaerobic forms and re-introduce oxygen to the region. Microorganisms that convert methane to carbon dioxide and water may also become established.

There are also inorganic reactions involving inorganic waste which involve (i). sulfate-containing materials and (ii) heavy metals. In the former case, plaster board (in this case, the sulfate is present in the form of gypsum) will be reduced under anaerobic, oxygen-deficient, conditions to produce a metal sulfide (via association with free metal ions). Under acidic conditions, the sulfate will be released as hydrogen sulfide (H_2S), which has the potential to present a serious hazard. The gas is toxic and can cause respiratory arrest if large concentrations are inhaled. Also, at concentrations above 100 ppm, the ability of a person to detect the gas is affected by rapid temporary paralysis of the olfactory nerves in the nose, leading to a loss of the sense of smell. This unusual property makes it extremely dangerous to rely totally on the sense of smell to warn of the presence of hydrogen sulfide.

Reduced sulfate, in the form of sulfide, will react with heavy metals (see above), producing a metal sulfide, which is comparatively immobile. Other insoluble salts such as metal carbonates may also be formed. Although these are potential pollutants, their immobility reduces their potential to migrate out of the landfill site boundary.

See also: Landfill, Landfill Gas, Waste.

Migration

Once gases are produced under the landfill surface, they generally move away from the landfill. Gases tend to expand and fill the available space, so that they move or migrate through the limited pore spaces within the refuse and soils covering of the landfill. The tendency of some landfill gases, such as methane, that is lighter than air, is to move upward, usually through the landfill surface. However, of the hydrocarbon derivatives, methane is the only one that is lighter than air. Higher-molecular-weight hydrocarbons such as ethane, propane, and butane are denser than air and may collect in pockets rather than migrate with the methane. This can cause problems when pockets are suddenly opened to the air (for example during landfill mining), and the flammability limit or flash point of the collected gas is reached.

In addition to the density phenomenon, upward movement of landfill gas can be inhibited by densely compacted waste or landfill cover material (e.g., by daily soil cover and caps). When upward movement is inhibited, the gas tends to migrate horizontally to other areas within the landfill or to areas outside the landfill, where it can resume its upward path. Basically, the gases follow the path of least resistance. Some gases, such as carbon dioxide, are denser

than air and will collect in subsurface areas, such as utility corridors. Three main factors influence the migration of landfill gases: diffusion (concentration), pressure, and permeability.

Diffusion is the natural tendency of a gas to reach a uniform concentration in a given space, whether it is a room or the atmosphere of the Earth. Gases in a landfill move from areas of high gas concentrations to areas with lower gas concentrations. Because gas concentrations are generally higher in the landfill than in the surrounding areas, landfill gases diffuse out of the landfill to the surrounding areas with lower gas concentrations.

Gases accumulating in a landfill create areas of high pressure in which gas movement is restricted by compacted refuse or soil covers and areas of low pressure in which gas movement is unrestricted. The variation in pressure throughout the landfill results in gases moving from areas of high pressure to areas of low pressure. Movement of gases from areas of high pressure to areas of lower pressure is known as convection. As more gases are generated, the pressure in the landfill increases, usually causing subsurface pressures in the landfill to be higher than either the atmospheric pressure or indoor air pressure. When pressure in the landfill is higher, gases tend to move to ambient or indoor air.

Gases will also migrate according to where the pathways of least resistance occur. Permeability is a measure of how well gases and liquids flow through connected spaces or pores in refuse and soils. Dry, sandy soils are highly permeable (many connected pore spaces), while moist clay tends to be much less permeable (fewer connected pore spaces). Gases tend to move through areas of high permeability (e.g., areas of sand or gravel) rather than through areas of low permeability (e.g., areas of clay or silt). Landfill covers are often made of low-permeability soils, such as clay. Gases in a covered landfill, therefore, may be more likely to move horizontally than vertically.

The direction, speed, and distance of landfill gas migration depend on a number of factors, such as (i) landfill cover, (ii) natural and man-made (anthropogenic) pathways, (iii) wind speed and direction, (iv) moisture, (v) groundwater levels, (vi) temperature, and (vii) gas pressure and barometric pressure.

If the landfill cover consists of relatively permeable material, such as gravel or sand, then gas will likely migrate up through the landfill cover. If the landfill cover consists of silts and clays, it is not very permeable; gas will then tend to migrate horizontally underground. If one area of the landfill is more permeable than the rest, gas will migrate through that area.

Drains, trenches, and buried utility corridors (such as tunnels and pipelines) can act as conduits for gas movement. The natural geology often provides underground pathways, such as fractured rock, porous soil, and buried stream channels, where the gas can migrate.

Wind speed and direction influence the fate of landfill gas naturally vented into the air at the landfill surface. The wind dilutes the gas with fresh air as it moves it to areas beyond the landfill. Wind speed and direction determine the concentration of the gas in the air, which can vary greatly from day to day, even hour by hour. In the early morning, for example, winds tend to be gentle and provide the least dilution and dispersion of the gas to other areas.

Wet surface soil conditions may prevent landfill gas from migrating through the top of the landfill into the air above. Rain and moisture may also seep into the pore spaces in the landfill and “push out” gases in these spaces. Water in the form of groundwater also influences gas movement. Variations in the groundwater table such as the water table is rising into an area will force the landfill gas upward.

Increases in temperature stimulate gas particle movement, tending also to increase gas diffusion, so that landfill gas might spread more quickly in warmer conditions. The landfill generally maintains a stable temperature; freezing and thawing cycles can cause the soil surface to crack, causing landfill gas to migrate in an upward direction and/or in a horizontal direction. Frozen soil over the landfill may provide a physical barrier to upward landfill gas migration, causing the gas to migrate further from the landfill horizontally through soil.

The difference between the soil gas pressure and barometric pressure allows gas to move either vertically or laterally, depending on whether the barometric pressure is higher or lower than the soil gas pressure. When the barometric pressure is falling, landfill gas will tend to migrate out of the landfill into surrounding areas. As barometric pressure rises, gas may be retained in the landfill temporarily as new pressure balances are established.

Monitoring

Landfill gas monitoring is the process by which gases that are released from landfills are electronically monitored.

Landfill gas production results from chemical reactions and microbes acting upon the waste as they begin to break down the waste. However, due to the constant production of landfill gas, pressure increases within the landfill provoke its release into the atmosphere and there is a clear need to monitor gas produced by landfills.

Techniques for monitoring of landfill gas include: (i) surface monitoring is used to check the integrity of caps on waste; this technique may give preliminary indications of gas migration off-site, (ii) 2. subsurface monitoring (gas probes) is used to enable point source monitoring of gas concentrations in the local environment around the probe; the monitoring system may contain a single probe or multiple probes (at different depths) at a single point; probes typically form a ring around a landfill, and the distance between probes varies (based upon several factors) and rarely exceeds 1,000 feet, (iii) excavated trenches and pits backfilled around standpipes provides means of measuring gas concentrations in shallow sites, (iv) gas monitoring boreholes or wells is the preferred method for measuring gas concentrations and sometimes flow rates both on and off site, (v) ambient air samplers are used to sample the air up-wind and down-wind of a landfill, over the period of several hours; samples are taken in special plastic bags or steel canisters and analyzed at a laboratory; when a landfill is situated in a location where the wind direction changes from day to night (such as near to a coastline), a 24-hour sampling period may be broken into day and night components, and (vi) the use of leachate wells may be used for gas monitoring but are not comparable with, or substitutes for specially designed gas monitoring points.

Power Generation

The gas generated in landfills can be tapped after the completion of the landfill, and when burnt as fuel has a calorific value approximately half that of natural gas. This is due to the fact that there is only approximately 60% v/v combustible methane in the gas (Table L-2). Generating electricity from landfill gas is clearly a better sustainable solution than merely trapping and not using it in any productive manner. It is a resource that should be employed. There is the added bonus for the site operators of extra generated financial revenue from the electricity sales. However, all of the environmental burdens still apply. The only offset is where electricity generation by non-renewable sources can be reduced.

Large municipal or industrial landfills produce gas that can be tapped to generate electricity. Microorganisms that live in organic materials such as food wastes, paper, or yard clippings cause these materials to decompose. This produces landfill gas, typically comprised of approximately 60% v/v methane and approximately 40% v/v carbon dioxide.

Landfill gas is collected from landfills by drilling "wells" into the landfills, and collecting the gases through pipes. Once the landfill gas is processed, it can be combined with natural gas to fuel conventional combustion turbines or used to fuel small combustion or combined cycle turbines. Landfill gas may also be used in fuel cell technologies, which use chemical reactions to create electricity, and are much more efficient than combustion turbines. However, use of the gas produced by landfills may reduce the harmful environmental impacts that would otherwise result from landfill operations. Landfill gas electricity generation offers major air quality benefits where landfills already exist or where the decision to build the landfill has already been made. Landfill gas power plants reduce methane emissions, a global climate change agent with twenty-three times the negative impact of carbon dioxide.

A landfill gas power plant burns methane that would otherwise be released into the atmosphere or burned off in a flaring process. Methane is a highly potent agent of global climate change, having approximately 23 times the negative impact on a pound-by-pound basis as carbon dioxide. Landfill gas combustion produces some carbon dioxide, but the impact of these emissions on global climate change is offset many times over by the methane emission reductions.

Landfill gas generators produce nitrogen oxides emissions that vary widely from one site to another, depending on the type of generator and the extent to which steps have been taken to minimize such emissions. Combustion of landfill gas can also result in the release of organic compounds and trace amounts of toxic materials, including mercury and dioxins, although such releases are at levels lower than if the landfill gas is flared.

There are few water impacts associated with landfill gas power plants. Unlike other power plants that rely upon water for cooling, landfill gas power plants are small, and therefore pollution discharges into local lakes or streams are typically quite small.

Pretreatment

After collecting the gas from the wells, the methane-rich gas is flared or pre-treated before being used in an energy recovery system. Treatment requirements depend on the end use application. When the landfill gas is required for energy or any other use, a rigorous pre-treatment of the gas is required.

Treatment systems can be divided into primary treatment processing and secondary treatment processing. Most primary processing systems include de-watering and filtration to remove moisture and particulates. Dewatering can be as simple as physical removal of free water or condensate in the landfill gas. However, it is common to remove water vapor using gas cooling and compression.

Secondary treatment systems are designed to provide much greater gas cleaning than primary gas cleaning systems. A large portion of the landfill gas consists of carbon dioxide which is non-combustible and therefore reduces the calorific value of the gas. Furthermore, in the presence of ambient moisture, acid gases produce acid rain, which is a well-known global environmental menace. The various gas cleaning systems may employ multiple cleanup processes depending on the gas specifications of the end use. Such processes include both physical and chemical treatments. The most common technologies used for secondary treatment are absorption and adsorption.

The removal of these toxic compounds can be done through dry or wet scrubbing processes. The scrubbing process is an operation in which one or more components of a gas stream are selectively absorbed into an absorbent. The term scrubbing is used interchangeably with “absorption” when describing this process. In wet scrubbing, a relatively non-volatile liquid is used as the absorbent. In dry scrubbing, a dry powder or semidry slurry are possible absorbents. Adsorption involves the binding of a particle to the surface. In this case, the surface is usually carbon or silica gel. There also exist advanced treatment technologies that remove carbon dioxide, non-methane organic compounds (NMOCs), and a variety of other contaminants in gas streams to produce a high-Btu gas.

Landfill gas can be upgraded to natural gas quality so that it can be used in the existing natural gas distribution network. One of the indices used to evaluate the quality of gas for comparative use is the Wobbe Index. The Wobbe Index allows for the comparison of the volumetric energy content of different gas fuels at different temperatures. Gas streams can possess varying heating values and relative densities but have the same Wobbe Index, *i.e.*, they will deliver the same heat and yield the same performance for a given process.

The upgrading process involves a series of complex processes which will result in the removal of elements such as, hydrogen sulfide, carbon dioxide, heavy hydrocarbon, siloxanes, nitrogen, and oxygen. Though the process used to remove such gasses is not new when applied to landfill gas, it may not be a cost-effective option. Upgraded landfill gas can also be used as chemical feedstock in the process industry such as in the production of diesel fuel and methanol. The process involves the upgrading of the landfill gas to chemical feedstock quality, hence rendering this option economically unattractive.

Production

Most landfill gas is produced by bacterial decomposition, which occurs when organic waste is broken down by bacteria naturally present in the waste and in the soil used to cover the landfill. Organic wastes include food, garden waste, street sweepings, textiles, and wood and paper products. Bacteria decompose organic waste in *four phases*, and the composition of the gas changes during each phase.

During the first phase of decomposition, aerobic bacteria (bacteria that live only in the presence of oxygen) consume oxygen while breaking down the long molecular chains of complex carbohydrates, proteins, and lipids that comprise organic waste. The primary by-product of this process is carbon dioxide. Nitrogen content is high at the beginning of this phase, but declines as the landfill moves through the four phases. The chemistry of this first phase continues until the available oxygen is depleted. This phase can last for days or months, depending on how much oxygen is present when the waste is disposed in the landfill. Oxygen levels will vary according to factors such as how loose or compressed the waste was when it was buried.

The *second phase* commences after the oxygen in the landfill has been consumed and is followed by the anaerobic phase (a process that does not require oxygen) in which the bacteria convert compounds created by aerobic bacteria into acetic acid, lactic acid, formic acid, and alcohol derivatives such as methanol and ethanol. The landfill becomes highly acidic and, as the acid derivatives mix with the moisture present in the landfill, the acids cause certain nutrients to dissolve, making nitrogen and phosphorus available to the increasingly diverse species of bacteria in the landfill. The gaseous by-products of these processes are carbon dioxide and hydrogen. If the landfill is disturbed or if oxygen is introduced into the landfill, microbial processes return those chemical processes typical of the *first phase* of decomposition.

The *third phase* commences when certain kinds of anaerobic bacteria consume the organic acids produced in the *second phase* and form acetate, an organic acid. This process causes the landfill to become a more neutral

environment in which methane-producing bacteria begin to establish themselves. The methane-producing and the acid-producing bacteria have a symbiotic relationship insofar as the acid-producing bacteria create compounds for the methanogenic bacteria to consume. Also, the methanogenic bacteria consume the carbon dioxide and acetate, too much of which would be toxic to the acid-producing bacteria.

The *fourth phase* of decomposition begins when both the composition and production rates of landfill gas remain relatively constant. The gas produced in this phase usually contains approximately 45% to 60% methane by volume, 40% to 60% carbon dioxide, and 2% to 9% other gases, such as sulfides. Gas is produced at a stable rate, typically for approximately 20 years. However, gas will continue to be emitted for 50 or more years after the waste is placed in the landfill (Crawford and Smith 1985). Gas production might last longer, for example, if greater amounts of organics are present in the waste, such as at a landfill receiving higher than average amounts of domestic animal waste.

As might be anticipated from the above paragraphs, there are many reactions that occur among the array of waste that is sent to landfill. Of the wastes that are disposed to landfill, municipal wastes are likely to play the greatest role in chemical reactions, with perhaps some arising as a result of hazardous waste. However, as the name suggests, inert wastes are chemically un-reactive. The majority of reactions occur as a result of the biodegradation, or breakdown, of organic material via microbial activity, but chemical interactions can also be seen to exist in the case of inorganic materials.

Many of the biochemical reactions in landfill sites occur as a result of the presence of the reactive, organic wastes which account for more than half of the typical household waste (Hester and Harrison, 2002 page 29). There are five major reaction processes involved with different microorganisms involved at each stage.

Although much more complex, the chemistry occurring at landfill sites is generally represented in the simplest form as the decomposition of cellulose and hemicellulose.

Cellulose:

Hemicellulose:

The reactions actually occur in stages, and cellulose (Section 2.1) and hemicellulose are not the only starting materials.

While the reactions described above are organic chemical reactions, there are also inorganic chemical reactions by which landfill gas is produced.

There are two prominent examples of reactions involving inorganic waste which are (i) sulfate-containing materials and (ii) heavy metals (Hester and Harrison 1995). In the former case, plaster board (in this case, the sulfate is present in the form of gypsum) will be reduced under anaerobic, oxygen-deficient, conditions to produce a metal sulfide (via association with free metal ions). Under acidic conditions, the sulfate will be released as hydrogen sulfide (H_2S), which has the potential to present a serious hazard. The gas is toxic and can cause respiratory arrest if large concentrations are inhaled. Also, at concentrations above 100 ppm, the human ability to detect the gas is affected by rapid temporary paralysis of the olfactory nerves in the nose, leading to a loss of the sense of smell which makes it extremely dangerous to rely totally on the sense of smell to warn of the presence of hydrogen sulfide.

Reduced sulfate, in the form of sulfide, will react with heavy metals (see above), producing a metal sulfide, which is comparatively immobile. Other insoluble salts such as metal carbonates may also be formed. Although these are potential pollutants, their immobility reduces their potential to migrate out of the landfill site boundary.

Recovery and Use

Landfill gas recovery is the process by which methane is collected from solid waste deposited in a landfill. Instead of escaping into the air, landfill gas can be captured, converted, and used as a renewable energy resource. Using landfill gas helps to reduce odors and other hazards associated with gas emissions.

Thus, instead of escaping into the air, landfill gas can be captured, converted, and used as a renewable energy resource. Using landfill gas helps to reduce odors and other hazards associated with gas emissions, and prevents methane from migrating into the atmosphere and contributing to local smog and global climate change. In addition, landfill gas energy projects generate revenue and create jobs in the community and beyond.

Landfill gas (LFG) is extracted from landfills using a series of wells and a blower/flare (or vacuum) system which is used to direct the collected gas to a central point where it can be processed and treated depending upon the ultimate use for the gas. From this point, the gas can be flared or beneficially used in a landfill gas energy project. Thus, the four main steps in the process are:

Landfill with waste in place → gas extraction wells
 Gas extraction wells → primary processing
 Primary processing → additional treatment
 Additional treatment → generation of alternative energy

There are many options available for converting LFG into energy. Different types of LFG energy projects are grouped below into three broad categories – (i) electricity generation, (ii) direct use of medium-Btu gas, and (iii) renewable natural gas.

A variety of technologies, including reciprocating internal combustion engines, turbines, microturbines, and fuel cells, can be used to generate electricity for onsite use and/or sale to the grid. The reciprocating engine is the most commonly used conversion technology for landfill gas electricity applications because of its relatively low cost, high efficiency, and size ranges that complement the gas output of many landfills. Gas turbines are typically used in larger landfill gas energy projects, while microturbines are generally used for smaller landfill gas volumes and in niche applications.

Cogeneration, also known as combined heat and power (CHP), projects use landfill gas to generate both electricity and thermal energy, usually in the form of steam or hot water. Several cogeneration projects using engines or turbines have been installed at industrial, commercial, and institutional operations, using engines or turbines. The efficiency gains of capturing the thermal energy in addition to electricity generation can make this project type an attractive option.

Direct use of landfill gas to offset the use of another fuel (for example, natural gas, coal, or fuel oil) occurs as the gas can be used directly in a boiler, dryer, kiln, greenhouse, or other thermal application. In these projects, the gas is piped directly to a nearby customer for use in combustion equipment as a replacement or supplementary fuel. Only limited condensate removal and filtration treatment are required, although some modifications of existing combustion equipment might be necessary.

Landfill gas can also be used directly to evaporate leachate. Leachate evaporation using landfill gas is an option for landfills where leachate disposal at a water resource recovery facility is unavailable or expensive. Landfill gas is used to evaporate leachate to a more concentrated and more easily discarded effluent volume.

Use for medium-Btu gas includes firing pottery and glass-blowing kilns; powering and heating greenhouses; and evaporating waste paint. Current industries using landfill gas include, for example: (i) the auto manufacturing industry, (ii) the chemicals production industry, (iii) the food and beverage processing industry, (iv) the pharmaceuticals industry, (v) the cement and brick manufacturing industry, (vi) the wastewater treatment industry, and (vii) the paper and steel production industries.

Landfill gas can be upgraded to renewable natural gas (RNG), a high-Btu gas, through treatment processes by increasing its methane content and, conversely, reducing the content of carbon dioxide, nitrogen, and oxygens. Renewable natural gas can be used in place of fossil natural gas, as pipeline-quality gas, compressed natural gas (CNG), or liquefied natural gas (LNG). Options for use of renewable natural gas include thermal applications, to generate electricity or as fuel for vehicles. The renewable natural gas can be used locally at the site where the gas is produced or can be injected into natural gas transmission or distribution pipelines for delivery to another location.

Landfilling

Provided that there is no shortage of land with suitable geological formations, landfill remains the principal final disposal route for the majority of wastes, even in highly industrialized countries. Over 70% of municipal wastes in North America and Western Europe are landfilled with little or no treatment. Where there is treatment, it is usually designed to reduce the volume of waste to be landfilled and includes compaction, shredding, baling, and incineration. Most solid wastes will directly be disposed of in sanitary landfills where there is some protection for citizens against airborne dust and litter, stench, rodents, and insects. Most of these nuisances can be prevented by the prompt covering of freshly dumped waste with soil.

In addition to landfill gas, the other product of landfill chemistry is landfill leachate. This is a liquid formed within a landfill site that is comprised of the liquids that enter the site (including rainwater) and the material that is leached from the wastes as the infiltrating liquids percolate downwards through the waste.

The main environmental problem associated with landfilling is pollution of groundwater. Rainwater percolating through solid waste tends to carry large amounts of pollutants to groundwater aquifers if the underlying strata are pervious or fissured. Thus, wells drawing from the aquifers will be extracting groundwater contaminated by the leachate; such a situation is often difficult to remedy. The leachate from solid wastes may have a pollution load up to 15 to 20 times higher than domestic wastewater.

Landfill tends to predominate as a waste disposal mode because it is regarded as an effective but low-cost method of disposal, also for hazardous waste. Even where other methods are more suitable for environmental reasons, the higher capital and (short-term) running costs mean that they cannot compete without government intervention. However, such cost calculations take no account of the longer term. In the long run, landfill of hazardous materials may impose a larger financial burden than other methods because of the high cost of ensuring that the site remains secure for the time it takes for the waste to be rendered harmless.

Disposal to landfill of untreated wastes other than inert material is becoming less acceptable, partly in response to a few well-documented instances where poorly-designed and operated landfills are giving rise to pollution problems, and partly as a result of greater public awareness of the issues involved.

Landfill Leachate

Leachate is the liquid that drains or leaches from a landfill, and it varies widely in composition regarding the age of the landfill and the type of waste that is contained in the landfill. The leachate may also be a useful starting material for the production of fuels and chemicals and should not be rejected as such until it (the leachate) has been tested for that potential.

The principal organic content of leachate (that could be the basis for the production of alternative fuels) formed during the breakdown processes varies with the location and the types of materials sent to the landfill. However, the organic content can be measured in terms of (i) the biochemical oxygen demand, BOD, (ii) the chemical oxygen demand, COD, or (iii) the total organic carbon, TOC. Also, the quality of municipal landfill leachate changes with time as the degradation of the waste continues inside the landfill. The degradation process is generally divided into five successive stages, namely, (i) aerobic, (ii) hydrolysis and fermentation, (iii) acetogenesis, (iv) methanogenic, and (v) aerobic phase (Figure 7.2). These processes are dynamic as each stage being dependent on the creation of a suitable environment by the preceding stage.

The concentration of certain compounds like nitrogen, ammonium, phosphorus, and chloride do not (typically) change significantly between the decomposition phases. Ammonia is probably the most important inorganic contaminant with the greatest potential to adversely impact on surface water and groundwaters. However, other components (such as heavy metals and sulfide derivatives) may be significant in certain circumstances. Iron and calcium are particularly important with respect to the precipitation of solids, while elevated salinity levels are ubiquitous. It should be noted that the site-specific discharge requirements will determine the components that require treatment or removal.

The generation of the leachate is caused principally by rain or melted snow percolating through waste deposited in a landfill. Once in contact with decomposing solid waste, the percolating water becomes contaminated, and if it then

flows out of the waste material, it is termed leachate. Additional leachate volume is produced during this decomposition of carbonaceous material producing a wide range of other materials including methane, carbon dioxide, and a complex mixture of organic acids, aldehydes, alcohols, and simple sugars.

One of the most important problems with designing and maintaining a landfill is managing the leachate that is generated when water passes through the waste. The leachate consists of many different organic and inorganic compounds that may be either dissolved or suspended. Regardless of the nature of the compounds, they pose a potential pollution problem for local ground and surface waters.

The use of landfill liners is now mandatory within both the United States and the European Union except where the waste is deemed inert. In addition, most toxic and difficult materials are now specifically excluded from landfilling. However, despite much stricter statutory controls, leachates from modern sites are found to contain a range of contaminants that may either be associated with some level of illegal activity or may reflect the ubiquitous use of a range of difficult materials in household and domestic products which enter the waste stream legally.

The physical appearance of leachate when it emerges from a typical landfill site is a yellow- or orange-colored cloudy liquid with a strong odor. The smell is typically acidic and offensive and may be very pervasive because of hydrogen-, nitrogen-, and sulfur-rich organic species such as mercaptans [thiols, i.e., organic compounds containing the thiol (SH) function].

Many factors influence the production and composition of leachate. One major factor is the climate of the landfill. For example, where the climate is prone to higher levels of precipitation, there will be more water entering the landfill and therefore more leachate generated. Another factor is the site topography of the landfill that influences the runoff patterns and again the water balance within the site.

Current leachate treatment options include recycling and re-injection, on-site treatment, discharge to a municipal water treatment facility, or a combination. However, with stricter regulations regarding ground and surface water contamination, landfills have to find new treatment alternatives.

The vast majority of wastes will produce a leachate of sorts if water is allowed to percolate through it, but the proportions of the leachate constituents are chiefly determined by the composition and solubility of the waste components. For example, if the waste is changing in composition (for example due to weathering or biodegradation), then leachate quality will change with time. This is particularly the case in landfills containing municipal waste.

At the start, the leachate produced is typically generated under the aerobic, oxygen-rich conditions, and this produces a complex solution with near neutral pH of 7.5. This process generally only lasts a few days or weeks and is relatively unimportant in terms of the quality of the leachate. However, the heat produced during aerobic decomposition can sometimes rise to as high as 80 to 90°C (175 to 195°F), and if this heat is retained, it can enhance the later stages of leachate production.

As waste decomposition progresses, the oxygen within the waste gradually becomes diminished, and the conditions become anaerobic. This initially creates high concentrations of soluble degradable organic compounds and an acidic pH. Ammonium and metal concentrations also rise during this phase. After several months or years, the onset of methanogenic conditions changes the pH of the leachate, making it more neutral or even slightly alkaline. As biodegradation nears completion, aerobic conditions may return, and the leachate will eventually cease to be hazardous to the environment.

The character of the leachate can be determined by means of the toxicity characteristic leaching procedure (TCLP).

Landfill Leachate Management

Leachate produced in a landfill is a liquid which has percolated through the waste, thereby leaching suspended and soluble materials that originate from or are products of the degradation of the waste. However, before considering the design of any leachate management system, it is important to consider the objectives that are to be achieved. Leachate needs to be controlled in a landfill for the following reasons: (i) to reduce the potential for seepage out of the landfill through the sides or the base either by exploiting weaknesses in the liner or by flow through its matrix, (ii) to prevent liquid levels rising to such an extent that rising liquid levels can spill over and cause pollution to

ditches, drains, and water courses or water systems, (iii) to influence the processes leading to the formation of landfill gas, chemical and biological stabilization of the landfill, (iv) to minimize the interaction between the leachate and the liner, and (v) in the case of above ground landfill, to ensure the stability of the waste.

Part of any leachate management plan should include definitive information that describes the manner in which the leachate is to be managed and measures put in place to minimize the generation of the leachate. Also, details on the leachate recirculation rate (if included in the plan) and a discussion of the means by which the leachate will be continually monitored as well as the performance and state of the liner which will relate to leachate recirculation, and the hydraulic loading of the landfills leachate collection and removal system should also be included. The plan should also address such items as the potential for leachate surface seeps, odor, remedial cleaning/flushing of the leachate collection, and removal system to ensure free-flow conditions and the potential for increased leachate leakage through the liner.

Landfill Mining

Landfill mining and reclamation (LFMR) is a process whereby solid wastes which have previously been landfilled are excavated and processed. The function of landfill mining is to reduce the amount of landfill mass encapsulated within the closed landfill and/or temporarily remove hazardous material to allow protective measures to be taken before the landfill mass is replaced.

In the process, mining recovers valuable recyclable materials, a combustible fraction that may serve as a precursor to fuel, soil, and landfill space. The aeration of the landfill soil is a secondary benefit as a consequence of regrading the landfills' future use. The overall appearance of the landfill mining procedure is a sequence of processing machines laid out in a functional conveyor system. The operating principle is to excavate, sieve, and sort the landfill material.

The concept of landfill mining was introduced when it was recognized that waste contains many resources with high value – the most notable of which are non-ferrous metals such as aluminum cans and metal scrap. The concentration of aluminum in many landfills is higher than the concentration of aluminum in bauxite from which the metal is derived. However, the potential to mine a fuel precursor such as wood or compressed organic material adds extra impetus to the concept of landfill mining.

Mining of landfill sites that were created for specific purposes is often the easiest form of landfill mining. However, mining municipal landfills has to be based on the expected content of the landfill.

Older landfills in the United States were often capped and closed, essentially entombing the waste. This can be beneficial for waste recovery. It can also create a higher risk for toxic waste and leachate exposure as the landfill has not fully processed the stewing wastes. Mining of bioreactor landfills and properly stabilized modern sanitary landfills provides its own benefits. The biodegradable wastes are more easily sieved out, leaving the non-biodegradable materials readily accessible. The quality of these materials for recycling and reprocessing purposes is not as high as initially recycled materials. However, materials such as aluminum and steel are usually excluded from this.

Landfill mining is most useful as a method to remediate hazardous landfills. Landfills that were established before landfill liner technology was well established often leak their unprocessed leachate into underlying aquifers. This is both an environmental hazard and also a legal liability. Mining the landfill simply to lay a safe liner is a last, but sometimes necessary resort.

In the mining process, an excavator or front end loader uncovers the landfilled materials and places them on a moving floor conveyor belt to be taken to the sorting machinery. A trommel (also known as a rotary screen) is a mechanical screening machine used to separate materials by size. First, a large trommel separates materials like appliances and fabrics. A smaller trommel then allows the biodegraded soil fraction to pass through leaving non-biodegradable, recyclable materials on the screen to be collected. An electromagnet is used to remove the ferrous material from the waste mass as it passes along the conveyor belt. A front end loader is used to move sorted materials to trucks for further processing. Odor control sprayers are wheeled tractors with a cab and movable spray arm mounted on a rotating platform. A large reservoir tank mounted behind the cab holds neutralizing agents, usually in liquid form, to reduce the smell of exposed wastes.

Excavators dig up waste mass and transport it, with the help of front end loaders, onto elevator and moving floor conveyor belts. The conveyor belts empty into a coarse, rotating trommel. The large holes in the screen

allow most wastes to pass through, leaving behind the over-sized, non-processable materials. The over-sized wastes are removed from inside the screen. The coarse trommel empties into the fine rotating trommel. The fine rotating trommel allows the soil fraction to pass through, leaving mid-sized, non-biodegradable, mostly recyclable materials. The materials are removed from the screen. These materials are put on a second conveyor belt where an electromagnet removes any metal debris. Depending on the level of resource, recovery material can be put through an air classifier which separates low-boiling organic material from high-boiling organic material. The separate streams are then loaded, by front end loaders, onto trucks either for further processing or for sale. Further manual processing can be done on site if processing facilities are too far away to justify the transportation costs.

Landfill mining is also possible in countries where land is not available for new landfill sites. In this instance, landfill space can be reclaimed by the extraction of biodegradable waste and other substances then refilled with wastes requiring disposal.

There are several proposals to use the mined landfill as feedstock to an anaerobic digester. However, there are some drawbacks to anaerobic digesters, mainly relating to the type of feedstock used. If the feedstock contains toxic chemicals (such as pesticides and wood preservatives), the digestate will be highly toxic through concentration of the toxic constituents. If the digestate cannot be used as a fertilizer, it becomes waste once more – but, having been mined from an old site, it will, more than likely, be classified as a toxic waste.

See also: Landfill Gas – Extraction, Landfill Waste – Gasification.

Landfill Sites

A landfill site is an area of land that has been specifically engineered to allow for the deposition of waste on to and into it. Municipal solid waste landfill sites are a large source of human-related methane emissions and, in some countries such as the United States, can account for up to 25% of these emissions. At the same time, methane emissions from landfills represent a lost opportunity to capture and use a significant energy resource.

The design of a landfill site should be such that it will prevent, or reduce as far as possible, negative effects on the environment, as well as the risks to human health arising from the landfilling of waste. It is essential that the design include methods, standards, and operational systems based on best practice which reflect progress in landfill management and containment standards. Landfill design is an interactive process incorporating (i) the conceptual design proposals, (ii) the findings of the environmental assessment and environmental monitoring results, (iii) risk assessment, and (iv) the fundamental objective behind waste management is that of sustainability.

The primary objective of landfill site design is to provide effective control measures to prevent or reduce as far as possible negative effects on the environment, in particular the pollution of surface water, groundwater, soil, and air, as well as the resulting risks to human health arising from landfilling of waste. The design concept for a landfill depends on the ground conditions, the geology and hydrogeology of the site, the potential environmental impacts, and the location of the landfill. The investigations for a landfill should provide sufficient information to enable the formulation of a site-specific design.

Landfill practice is dynamic in that it will change with both advances in technology and changes in legislation. To incorporate such advances and changes, a periodic review of the design should be carried out, as the lifespan of a landfill site from commencement to completion is long compared to other construction projects. Generally, landfills are constructed on a phased basis during which all environmental media that may be significantly impacted through the life of the landfill should be considered.

A liner must be provided for the protection of soil, groundwater, and surface water. The liner system may consist of a natural or artificially established mineral layer combined with a geosynthetic liner that must meet prescribed permeability and thickness requirements.

An efficient leachate collection system may have to be provided to ensure that leachate accumulation at the base of the landfill is kept to a minimum. The leachate system may consist of a leachate collection layer with a pipe network to convey the leachate to a storage or treatment facility.

The accumulation and migration of landfill gas must be controlled. Landfill gas may need to be collected with subsequent treatment and utilization, or disposal in a safe manner through flaring or venting.

Provisions should be incorporated in the design to minimize and control nuisances arising from the construction, operation, closure, and aftercare phases of the landfill. Nuisances that may arise from landfilling include noise, odors, dust, litter, birds, vermin, and fires.

Consideration must be given to the stability of the subgrade, the basal liner system, the waste mass, and the capping system. The subgrade and the basal liner should be sufficiently stable to prevent excessive settlement or slippages. The hydraulic uplift pressure on the lining system due to groundwater must be considered. The method of waste emplacement should ensure stability of the waste mass against sliding and rotational failure. The capping system should be designed to ensure stability against sliding. Visual appearance and landscape consideration should be given to the visual appearance of the landform during operation and at termination of landfilling and its impact on the surrounding landforms.

The designer must also consider the manner of site development and the necessary site infrastructural requirements during landfill operation and restoration. Landfill sites should be developed on a phased basis. Site infrastructure should include for the provision of (i) site accommodation, (ii) weighbridge, (iii) waste inspection area, (iv) wheel wash, (v) site services, and (vi) security fencing.

The designer should consider the intended after-use of the facility. It should be compatible with the material components and physical layout of the capping system, the surrounding landscape, and current land use zoning as specified in the relevant development plan.

Landfill Sites – Bioreactor

An innovative approach to municipal solid waste disposal, which actually encourages rapid waste decomposition and speed stabilization, is the bioreactor landfill. The enhanced waste degradation and stabilization, carried out by the indigenous microbial populations within the waste, is accomplished through control of moisture, temperature, pH, nutrients, etc. The enhanced microbiological processes within a bioreactor can transform and stabilize the decomposable organic waste within 5 to 10 years of implementation, compared with many decades for conventional landfills where wastes are essentially sealed off from air and moisture.

The bioreactor landfill was initially defined by the Solid Waste Association of North America (SWANA) as (quote) a sanitary landfill operated for the purpose of transforming and stabilizing readily and moderately decomposable organic waste constituents within 5 to 10 years following closure by purposeful control to enhance microbiological processes (end quote). The bioreactor landfill significantly increases the extent of waste decomposition, conversion rates, and process effectiveness over what would otherwise occur within the landfill. SWANA now defines a bioreactor landfill as (quote) any permitted Subtitle D landfill or landfill cell, subject to New Source Performance Standards/Emissions Guidelines (NSPS/EG), where liquid or air, in addition to leachate and landfill gas (landfill gas) condensate, is injected in a controlled fashion into the waste mass in order to accelerate or enhance biostabilization of the waste (end quote). However, there is still disagreement among scientists and engineers as to the precise definition for a bioreactor landfill.

A bioreactor landfill is typically a municipal solid waste landfill site that operates to rapidly transform and degrade organic waste. The increase in waste degradation and stabilization is accomplished through the addition of liquid and air to enhance microbial processes. There are three types of bioreactor landfills: (i) an aerobic landfill, (ii) an anaerobic landfill, and (iii) a hybrid landfill, which is a combination of the aerobic process and the anaerobic process.

In an aerobic bioreactor landfill, leachate is removed from the bottom layer, piped to liquids storage tanks, and re-circulated into the landfill in a controlled manner. Air is injected into the waste mass using vertical or horizontal wells to promote aerobic activity and accelerate waste stabilization. In an anaerobic bioreactor landfill, moisture is added to the waste mass in the form of re-circulated leachate and other sources to obtain optimal moisture levels. Biodegradation occurs in the absence of oxygen (anaerobically) and produces landfill gas. Landfill gas (primarily methane) can be captured to minimize greenhouse gas emissions and can be used for energy projects. Hybrid (Aerobic-Anaerobic) – The hybrid bioreactor landfill accelerates waste degradation by employing a sequential aerobic-anaerobic treatment to rapidly degrade organics in the upper sections of the landfill and collect gas from lower sections. Operation as a hybrid results in the earlier onset of methanogenesis compared to aerobic landfills. In all cases, leachate is formed when rain water filters through wastes placed in a landfill. When this liquid comes in

contact with buried wastes, it leaches, or draws out, chemicals or constituents from those wastes. Thus, in contrast to conventional municipal solid waste landfills, bioreactors are designed and operated to enhance microbial processes significantly, to degrade and stabilize the organic constituents of the waste.

In a bioreactor landfill, leachate and additional liquid are returned to the landfill until the liquid holding capacity of the waste is achieved. Leachate drained from the waste is recovered and recirculated to maintain the moisture content of the waste and distribute nutrients for microbial degradation. A distinction should be made between the bioreactor landfill operation and the conventional leachate recirculation performed at conventional municipal solid waste landfill sites. The bioreactor process requires significant liquid addition to maintain optimal conditions.

Leachate alone is usually insufficient to sustain the bioreactor needs. Water or non-toxic, non-hazardous liquids and semi-liquids are suitable amendments to supplement leachate. At the closure of a bioreactor landfill site, the following should be observed: (i) the leachate quantity will be amenable to on-site treatment with limited need for off-site transfer, treatment, and/or disposal, (ii) the generation of the landfill gas generation should be in decline, and (iii) the long-term environmental risk will be minimized.

Landfill Sites – Construction and Debris

A construction and debris landfill site (sometimes designated as an *inert landfill site*) is devoted exclusively to construction and debris wastes that are chemically and physically stable and do not undergo decomposition. Such wastes are sand, bricks, concrete, or gravel. The waste, as the name implies, is generated from construction, renovation, repair, and demolition structures such as residential and commercial buildings, roads, and bridges. The composition of construction and debris waste varies for these different activities and structures.

Overall, construction and debris waste is composed mainly of wood products, asphalt, drywall, and masonry; other components often present in significant quantities are metals, plastics, earth, shingles, insulation, paper, and cardboard. Construction and debris also contain wastes that may be hazardous, potentially toxic and problematic, such as adhesives, leftover paint, excess roofing cement, waste oils, grease and fluids, batteries, fluorescent bulbs, appliances, carpet, and treated or untreated wood. It is not prudent to dispose of such waste in municipal solid waste landfill sites. Construction and debris landfills are easier to site because demolition materials are for the most part inert unless contaminated from an external source introduced at the construction/demolition site; therefore, the environmental impact is considered minimal.

Landfill Sites – Hazardous Waste

A *hazardous waste landfill site* is a waste disposal site that is units constructed to specific design criteria and which receive wastes meeting the local definition of hazardous waste. These landfills are generally constructed to be secure repositories for material that presents a serious hazard to human health, such as high-level radioactive waste. They are restricted, by permit or law, to the types of waste that they may handle (chemical vs. radioactive, liquid vs. dry). Double liner systems are the norm for hazardous waste landfills.

Thus, these types of facilities are disposal facilities for the more toxic chemicals and dangerous by-products. These landfills must be extremely well engineered to reduce any chance of the escape of hazardous compounds into the environment. These landfills are restricted, by permit or law, to the types of waste that they may handle (chemical vs. radioactive, liquid vs. dry). Double liner systems are the norm for hazardous waste landfills.

See also: Hazardous Waste, Waste.

Landfill Sites – Manual

Manual landfills have been developed in South and Central American cities where population sizes are less than 50,000 inhabitants. Manual landfills are similar in design to mechanized ones except for the size and the equipment required. These landfills have the capacity to receive 10 to 50 tons per day. The use of heavy equipment may be

required but only for periodic preparation for the terrain and the accumulation of cover material. Otherwise, all key steps for landfill preparation are carried out manually including cell preparation, compaction, and daily cover.

In some cases, a manual landfill site may also be designated as a *dump site* which is a landfill site that is not engineered with the special protective measures required by a sanitary landfill. Dump sites are most common in rural, remote, and developing areas. Many jurisdictions prohibit the use of a non-sanitary landfill for the disposal of municipal solid waste. Other jurisdictions that do allow dumps may require them to be constructed according to some engineering standard to mitigate the risk of environmental contamination, such as by (i) limiting the angle of the slope, (ii) requiring compaction of the waste in place, or (iii) ensuring that the cell is sufficiently high enough above the groundwater table to mitigate the potential for contamination of the water.

Landfill Sites – Municipal Solid Waste

Conventional municipal solid waste landfill sites (MSWLF) generally contain (less toxic) wastes from sources such as private homes, institutions, schools, and businesses without hazardous wastes. Modern sanitary landfills are engineered to protect public health and the environment and usually include detection and prevention of hazardous waste from entering the landfill, appropriate cover material for active cells and closed landfill, disease vector and explosive gas control, air monitoring, facility access, run-on control, run off control and surface water requirements, restrictions on liquids entering the cells, and record-keeping requirements. An engineered municipal solid waste landfill site comprises a liner, leachate collection and removal system, final cover, gas management, and a groundwater monitoring system.

Landfill Sites – Sanitary

A *sanitary landfill site*, also called a modern, engineered, or secure landfill site, typically has physical barriers such as liners and leachate collection systems, and procedures to protect the public from exposure to the disposed wastes. The term sanitary landfill normally refers to those sites where municipal solid waste is sent for disposal as well as other wastes that are high in organic material. In some countries, all landfills are sanitary landfills.

Landfill Sites – Surface Impoundment

A surface impoundment is a natural topographic depression, man-made excavation, or diked area formed primarily of earthen materials (although it may be lined with man-made materials), which is designed to hold an accumulation of liquid wastes or wastes containing free liquids. Examples of surface impoundments are holding, storage, settling, and elevation pits, ponds, and lagoons. If the pit, pond, or lagoon is intended for storage or holding without discharge, it is considered to be a surface impoundment. This information can be used for direct calculation of the quantity of a listed chemical and/or compound disposed of in this manner. This disposal method is often considered as a release to land; however, chemicals in the impoundment may be released to air by volatilization, collected as sludge and removed, or biodegraded. Any releases from the impoundment should be accounted for in release totals to air, water, land, or offsite disposal.

The impoundments must be properly lined to prevent infiltration of chemical constituents into the soil and protect groundwater quality. The liner is considered as part of the impoundment, and waste migration into the liner is allowed. The liner must therefore have sufficient strength and thickness to prevent failure due to pressure gradients, be chemically compatible with the migrating waste constituents, be protected from climatic conditions, installation and operation stresses, and prevents gradients caused due to settlements, compression or uplift.

A surface impoundment unit used for disposal of hazardous waste must have two or more liners and a leachate collection and removal system between such liners. The liner system must include a top liner made of geomembrane. The requirements for a hazardous waste landfill are similar to those for a surface impoundment. The system must have a leachate collection system, a top flexible membrane liner (FML), a leachate collection, and a detection and removal system.

A sustainable flood retention basin (SFRB) is defined as an impoundment or wetland that has the potential or predefined role for use in flood defense and pollution control, which is accomplished cost-effectively through best

management practice achieving flood risk management while enhancing sustainable drainage, pollution reduction, biodiversity, green space, and recreational opportunities for society (Yang *et al.*, 2011). The sustainable flood retention basin must be capable of being maintained at a steady level without exhausting natural resources, harming the environment, and causing severe ecological damage. The functions of retention basins are therefore diverse. Moreover, one basin often has multiple and mixed functions and the classification of a sustainable flood retention basin is required to allow for better understanding and communication of the status and function of any basin.

Whatever the classification, the landfill site should be designed in such a fashion that there is minimal harm to the environment and that the land may be restored in some way after the period of waste disposal. Despite its connotations as an *out of sight, out of mind* solution (Hester and Harrison, 2002, page 28), landfill is a well-used method of waste management that is applied to the majority of solid wastes in many countries.

See also: Waste.

Landfill Waste – Gasification

There is also the potential for the gasification of any organic waste material that is mined from the landfill as a solid or semi-solid.

A waste gasification facility converts the waste into a pressurized gas mixture which is then passed through a cleanup system to remove particulate matter and tar vapor, and finally used to turn turbines in a power plant. The remaining gas is a mixture of carbon monoxide, hydrogen, water vapor, and carbon dioxide. Finally, the particulates and tar are thermally treated (pyrolyzed) to produce carbon monoxide.

Any hydrogen produced that is not used as a constituent of synthesis gas can be removed and stored for use in hydrogen fuel cells. Waste gasification does produce some carbon dioxide that needs attention. There is the thought that although the carbon dioxide is produced from a renewable organic source, it has a short atmospheric residence time and therefore does not contribute to global warming. On this basis, carbon dioxide from biomass is acceptable but carbon dioxide from a fossil fuel is unacceptable.

The goal of using fuels from alternative sources is not only to supplement the dwindling supplies of fossil fuels but also to reduce the emissions of greenhouse gases. Carbon dioxide is a greenhouse gas – no matter what the source. To consider the carbon dioxide allowable because it is from a biomass-based process is, in any sense, playing with numbers and using a statistical means to justify the end.

See also: Gasification, Gasification of Biomass, Synthesis Gas.

Landfill Waste – Power Generation

Large municipal or industrial landfills produce gas that can be tapped to generate electricity. Microorganisms that live in organic materials such as food wastes, paper, or yard clippings cause these materials to decompose. This produces landfill gas, typically comprised of roughly 60% methane and 40% carbon dioxide.

The gas generated in landfills can be tapped after the completion of the landfill, and when burnt as fuel, has a calorific value approximately half that of natural gas. This is due to the fact that there is only approximately 60% combustible methane in the gas created and this has a calorific value of approximately 450 Btu/ft³ compared to approximately 900 Btu/ft³ for purified natural gas.

Generating electricity from landfill gas is clearly a better sustainable solution than merely trapping and not using it in any productive manner. It is a resource that should be employed. There is the added bonus for the site operators of extra generated financial revenue from the electricity sales. However, all of the environmental burdens still apply, but there is the offset that electricity generation by non-renewable sources can be reduced.

Landfill gas is collected from landfills by drilling wells into the landfills, and collecting the gases through pipes. Once the landfill gas is processed, it can be combined with natural gas to fuel conventional combustion turbines or used to fuel small combustion or combined cycle turbines. Landfill gas may also be used in fuel cell technologies, which use chemical reactions to create electricity, and are much more efficient than combustion turbines. However, use of the gas produced by landfills may reduce the harmful environmental impacts that would otherwise result from

landfill operations. Landfill gas electricity generation offers major air quality benefits where landfills already exist or where the decision to build the landfill has already been made.

A landfill gas power plant burns methane that would otherwise be released into the atmosphere or burned off in a flaring process. Landfill gas combustion produces some carbon dioxide, but the impact of these emissions on global climate change is offset many times over by the methane emission reductions.

Landfill gas generators produce nitrogen oxides emissions that vary widely from one site to another, depending on the type of generator and the extent to which steps have been taken to minimize such emissions. Combustion of landfill gas can also result in the release of organic compounds and trace amounts of toxic materials, including mercury and dioxins, although such releases are at levels lower than the releases when the landfill gas is flared.

Unlike other power plants that rely upon water for cooling, landfill gas power plants are small, and therefore pollution discharges into local lakes or streams are typically quite small.

Leaching

Leaching is a natural process by which water-soluble substances (such as water-soluble chemicals or hydrophilic chemicals) are washed out from soil or waste disposal areas (such as a landfill). These leached out chemicals (leachates) can cause pollution of surface waters (ponds, lakes, rivers, and the sea) and sub-surface water groundwater aquifers).

The solvent used for leaching processes can be a subcritical liquid or a supercritical fluid. It must compete with forces binding the solute to the solid in order to solubilize it. These forces can be very weak, as with oil contamination on mill scale, of intermediate strength, as with adsorbed contaminants on clay or activated carbon, or strong, as with chemical binding of metals in ores. Correspondingly, the solvents used to dissolve the solute can vary from those having purely physical interactions through those having weak chemical interactions (such as polar forces), through those having intermediate strength chemical forces (such as chemical complexing), to those exhibiting the strong chemical forces of ionic bonding. Once the solute has been solubilized in the solvent by the leaching process, it can be treated further by other processes, including liquid-liquid extraction, to purify and recover the solute, i.e., the leachate.

The basic difference between leaching and the other extraction processes is that a *solid* rather than a fluid must be intimately mixed with and then separated from the solvent. This may require longer residence times for the solvent-solid mixture to come to equilibrium in each contacting stage. This is especially true if the solid is porous, and the solvent must diffuse into the pores to dissolve the desired solute. The solvent needs to fulfill two major functions to be a good leaching solvent.

First, the solvent must be able to desorb the desired solute from the surface of the solid, and, second, it should be able to dissolve the released solute to keep it from being mechanically remixed with the feed solids and trapped in the matrix during phase separation. Thus, choosing a suitable solvent for a leaching operation requires some knowledge of the nature of the binding forces between the feed solids and the components to be recovered from them. For example, clay minerals tend to adsorb polar molecules more strongly than non-polar molecules. Thus, while clay minerals are effective for adsorbing polar components from non-polar solutions such as hydrocarbons, they are not effective for recovering organics from aqueous solutions because the strongly polar water molecules occupy the adsorption sites and cannot be displaced by the less polar organic molecules. However, to recover organics from spent clay, a small amount of water added to a good solvent for the organics will displace the organics from the surface of the clay very effectively. This permits the organic constituents to dissolve in the solvent and be recovered from the solids.

In contrast to the clay minerals, the carbon adsorbents tend to adsorb non-polar molecules more strongly than polar ones. This permits carbon to be used effectively to adsorb organics from aqueous wastewater solutions. However, to regenerate the spent carbon adsorbent requires a solvent of low solubility parameter to compete effectively for the weakly interactive adsorption sites on the carbon. The solvent can then dissolve the relatively non-polar solute released from the adsorbent. This, along with ease of solvent recovery from solids, is what made supercritical fluids look like attractive solvents for regenerating spent carbon from adsorption processes.

In the environment, leaching is the process by which chemicals or radionuclides are released from the solid phase into the water phase under the influence of mineral dissolution, desorption, and complexation processes as affected by pH, redox chemistry, and biological activity. The process itself is universal, as any material exposed to contact with water will leach components from its surface or its interior depending on the porosity of the material. In terms of the effect of pH (acidity or alkalinity), the leachability of a chemical; (i.e., the ability of the chemical to be leached from the source) can be enhanced by the occurrence of acid rain which can enhance the solubility of the chemical in the acidified water.

Thus, leaching is the process by which (in the current context) contaminants are released from the solid phase into the water phase under the influence of dissolution, desorption, or complexation processes as affected by acidity or alkalinity (the pH value). The process itself is universal, as any material exposed to contact with water will leach components from its surface or its interior depending on the porosity of the material under consideration. Leaching often occurs naturally with soil contaminants such as chemicals, with the result that the chemicals end up in potable waters.

Many chemicals occur in a mixture of different components in a solid (such as the metallic deposits on petroleum coke or metals in spent catalysts). In order to separate the desired solute constituent or remove an undesirable solute component from the solid phase, the solid is brought into contact with a liquid during which time the solid and liquid are in contact and the solute or solutes can diffuse from the solid into the solvent, resulting in separation of the components originally in the solid (leaching, liquid-solid leaching). In addition, leaching may also be referred to as extraction because the chemical is being extracted from the solid or the process may also be referred to as washing because a chemical is removed from a solid with water.

Leaching is affected by (i) the texture of the solid that holds the chemical to be leached, (ii) structure of the chemical to be leached, and (iii) water content of the solid which holds the chemical. If the solid holding the chemical is soil, then in terms of soil texture, for example, the proportions of sand, silt, and clay affect the movement of water through the soil. Coarse-textured soil contains more sand particles which have large pores, and the soil is highly permeable which allows the water to move rapidly through the pore system. On the other hand, chemicals (such as phosphate pesticides) carried by water through coarse-textured soil are more likely to reach and contaminate groundwater. On the other hand, clay-textured soils have low permeability and tend to retain more water and adsorb more chemicals from the water. This slows the downward movement of chemicals, helps increase the chance of degradation and adsorption to soil particles, and reduces the chance of groundwater contamination.

In terms of soil structure, loosely packed soil particles allow speedy movement of water through the soil while tightly compacted soil holds water back and does not allow the water to move freely through it. Plant roots penetrate soil, creating excellent water channels when they die and rot away. These openings and channels may permit relatively rapid water movement even through soil that contains clay minerals. On the other hand, the amount of water already in the soil has a direct bearing on whether rain or irrigation results in the recharging of groundwater and possible leaching of chemicals into an aquifer. Soluble chemicals are more likely to reach groundwater when the water content of the soil approaches or is at saturation. Saturation is typical in the spring when rain and snowmelt occur, but when soil is dry, the added water just fills the pores in the soil near the soil surface, making it unlikely that the water will reach the groundwater supply.

Leaching processes introduce chemicals into the water phase by solubility and entrainment. In addition, the leaching processes that move chemicals from soil can have a variety of potential scenarios – the spill of chemicals on to soil may cause partitioning in water that has been in contact with the contamination.

Lean Gas and Rich Gas

Lean gas is a gas stream (especially a natural gas stream) in which methane is the major constituent and is the residual gas from the absorber after the condensable constituents have been removed from the wet gas. On the other hand, rich gas is a gas stream that contains higher-molecular-weight (and higher-boiling) hydrocarbon derivatives than a lean gas. Its liquid content adds important economic value to developments containing this type of fluid.

In terms, liquefied natural gas (LNG) that is of a specification with extremely low, high heating value (HHV). Lean liquid stream is predominately methane with some minor quantities of ethane and lean liquefied natural gas may be required to meet fuel quality specifications and standards required by liquefied natural gas-powered vehicles and other liquefied natural gas-fueled equipment. Leaner liquefied natural gas can be produced through the extraction of the heaviest components, namely the liquefied natural gas, propane, and butane. Rich liquefied natural gas with high heating value is also produced for some market segments.

On the other hand, rich liquefied natural gas is a gas stream that has a heat content that is higher than the standard on many North American pipelines, since it contains small amounts of natural gas liquids (NGLs). The natural gas liquids – typically ethane, propane, and butane – can be extracted following regasification and used as petrochemical feedstocks.

Life Cycle Impacts

The energy used to manufacture fertilizer and the fuel used to operate farm equipment at farms that grow biomass energy crops reduce the net energy produced from biomass power plants that use biomass crop systems for feedstock.

Life-cycle analyses of biomass have been conducted for various configurations of power plants and fuel supplies to determine the net energy available using biomass fuels for power generation. The results indicate that only 2% to 8% of the useful energy output of a biomass power plant fueled by a biomass crop system is required for fertilization, planting, cultivation, harvesting, transportation, and fuel preparation. In other words, the amount of useful energy output from a biomass power plant is 12.5 to 50 times as much as the energy required to grow, harvest, transport, and process biomass from biomass crop systems. While these studies have not addressed the implications of using forest-derived fuels instead of energy crops.

The transportation energy use for forest biomass may or may not be higher than for biomass crops. Transportation vehicles are similar, and so transportation distance would be the primary reason for differences in transportation energy use between biomass crops and forest biomass.

The net environmental benefits of ethanol depend on how much energy is used to grow and process the biomass feedstock. The ethanol fuel industry has made great efficiency gains. The current energy balance for ethanol is 1.34; that is, for every unit of energy used in growing and producing ethanol, approximately one-third more energy is produced as fuel. Current trends predict that this ratio will increase to 2.09 for corn ethanol and 2.62 for cellulose ethanol.

Ethanol made from corn will result in a net air emissions reduction of 20%. Using soybeans will reduce net emissions nearly 80%. Cellulose-based ethanol can lead to even greater decreases since this type of biomass can be used to generate more electricity than is used in the production of ethanol fuel. The surplus power can then be sold, displacing the burning of fossil fuels for electricity production. This can result in a net reduction greater than 100%. In the case of ethanol from corn stover, the reduction can be as much as 113%. Another study used total fuel cycle analysis to compare reformulated gasoline (RFG) to E10 (a mixture of 10% ethanol with 90% unleaded gasoline by volume) and E95 (a mixture of 95% ethanol with 5% unleaded gasoline). 91 E95 produces only 9% of the net CO₂ produced by the RFG fuel cycle. If one takes into account the carbon sequestration benefits, E95 produces only 4% of the total CO₂ produced by the RFG cycle.

Light Ends

The term light ends is a general collective term that is used to describe the gaseous and more volatile liquid hydrocarbon derivatives produced in a refinery or, in the present context, during the thermal treatment of biomass to produce gases and bio-oil. The term is equally applicable to a mixture of low-boiling products (i.e., gases) produced from alternate energy sources. The term usually includes the C₁ to C₄ hydrocarbon derivatives but may also include the C₅ and C₆ hydrocarbon derivatives (Table L-3).

Table L-3 Examples of the hydrocarbon constituents of light ends*.

Constituent	Formula	Boiling point	
		°C	°F
Alkanes			
Methane	CH ₄	-182	-296
Ethane	CH ₃ CH ₃	- 89	-128
Propane	CH ₃ CH ₂ CH ₃	-42	-44
n-Butane	CH ₃ CH ₂ CH ₂ CH ₃	-1	31
n-Pentane	CH ₃ CH ₂ CH ₂ CH ₂ CH ₃	36	97
n-Hexane	CH ₃ CH ₂ CH ₂ CH ₂ CH ₂ CH ₃	69	156
Alkenes*			
Ethylene	CH ₂ =CH ₂	-104	-155
Propylene	CH ₃ CH=CH ₂	-48	-54
Butylene-1	CH ₃ CH ₂ CH=CH ₂	-6	21
Butylene-2	CH ₃ CH=CHCH ₃	1	34

*Typically produced in thermal decomposition processes.

Light ends are produced in relatively small quantities during some processes (depending upon the temperature and the residence time of the feedstock in the hot zone). When a naphtha component at the time of its manufacture is passed through a condenser, most of the light ends do not condense and are withdrawn and handled as a gas. A considerable part of the light ends, however, can remain dissolved in the condensate, thus forming a liquid with a high vapor pressure.

A light ends unit consists of a sequence of distillation processes to separate the overhead distillate product from the atmospheric distillation column into five streams consisting of (i) methane, (ii) ethane, (iii) propane, (iv), butane (v), low-boiling naphtha, and (vi) high-boiling naphtha. The fractions consisting of methane, ethane, propane, and butane are often used as feedstock for chemicals production. Propane and butane are sold as liquefied petroleum gas (LPG). The low-boiling naphtha fraction that consists of the low-boiling paraffin hydrocarbons pentane (C₅H₁₂) and hexane (C₆H₁₄) is used as a blend-stock for gasoline production as may the high-boiling naphtha fraction, but if the high-boiling naphtha fraction is rich in cycloalkane derivative (also known as naphthene derivatives), it may be sent to a catalytic reforming unit to produce blend-stock for high-octane gasoline.

Gases and low-boiling liquids (such as light ends) with high vapor pressures may be stored in refrigerated tanks or in tanks capable of withstanding the pressures developed by the gases dissolved in the liquid. The more usual procedure, however, is to separate the light ends from the liquid by a distillation process generally known as *stabilization*. Enough of the light ends are removed to make a stabilized liquid, that is, a liquid with a low enough vapor pressure to permit its storage in ordinary tanks without loss of vapor.

Liquids with high vapor pressures may be stored in refrigerated tanks or in tanks capable of withstanding the pressures developed by the gases dissolved in the liquid. The more usual procedure, however, is to separate the light ends from the liquid by a distillation process generally known as *stabilization*. Enough of the light ends are removed to make a stabilized liquid, that is, a liquid with a low enough vapor pressure to permit its storage in ordinary tanks without loss of vapor. The simplest stabilization process is a stripping process. Low-boiling naphtha from a crude tower, for example, may be pumped into the top of a tall, small-diameter fractional distillation tower operated under a pressure of 50-80 psi. Heat is introduced at the bottom of the tower by a steam reboiler. As the naphtha cascades down the tower, the light ends separate and pass up the tower to leave as an overhead

product. Since reflux is not used, considerable amounts of liquid hydrocarbon derivatives pass overhead with the light ends.

Although the constituents of the light ends fraction do occur naturally as natural, gas and crude oil gases, they are also produced (in the case of crude oil) as a result of thermal (catalytic and non-catalytic) processes.

See also: Light Ends, Refining.

Light Hydrocarbons

Light hydrocarbon derivatives (low-boiling hydrocarbon derivatives) are those hydrocarbon derivatives with a molecular weight less than that of heptane (C_7H_{16} , molecular weight = 100). Typical hydrocarbons of the light ends group are the gases: methane, ethane, propane, and butane isomers, although on occasion, the pentane (C_5) isomers and the hexane (C_6) isomers may also be included in the light ends group.

See also: Light Ends, Refining.

Lightning

Lightning is a form of energy that occurs as an electrostatic discharge during which two electrically charged regions in the atmosphere or ground temporarily equalize themselves, causing the instantaneous release energy. This discharge may produce a wide range of electromagnetic radiation, from hot plasma created by the rapid movement of electrons to visible light. The three main kinds of lightning are distinguished by where they occur and are (i) inside a single thundercloud, (ii) between two different clouds, or (iii) between a cloud and the ground.

As a thundercloud moves over the surface of the Earth, an equal electric charge (of opposite polarity) is induced on the surface of the Earth (an image charge) underneath the cloud. The induced positive surface charge, when measured against a fixed point, will be small as the thundercloud approaches, increasing as the center of the storm arrives and dropping as the thundercloud passes. The referential value of the induced surface charge could be roughly represented as a bell curve. The oppositely charged regions create an electric field within the air between them, and this electric field varies in relation to the strength of the surface charge on the base of the thundercloud – the greater the accumulated charge, the higher the electrical field.

Since the late 1980s, there have been several attempts to investigate the possibility of harvesting energy from lightning. While a single bolt of lightning carries a relatively large amount of energy (approximately 5 billion joules), this energy is concentrated in a small location and is passed during an extremely short period of time (milliseconds); therefore, extremely high electrical power is involved. It has been proposed that the energy contained in lightning be used to generate hydrogen from water, or to harness the energy from rapid heating of water due to lightning, or to use inductors spaced far enough away so that a safe fraction of the energy might be captured.

A technology capable of harvesting lightning energy would need to be able to rapidly capture the high power involved in a lightning bolt. Several schemes have been proposed, but the ever-changing energy involved in each lightning bolt have rendered lightning power harvesting from ground based rods impractical. Additionally, lightning is sporadic, and therefore energy would have to be collected and stored; it is difficult to convert high-voltage electrical power to the lower-voltage power that can be stored. Another major challenge when attempting to harvest energy from lightning is the impossibility of predicting when and where thunderstorms will occur. Even during a storm, it is difficult to tell where exactly lightning will strike.

Lignans

Lignans are traditionally defined as a class of secondary metabolites that are derived from the oxidative dimerization of two or more phenylpropanoid units. Despite the common biosynthetic origins, lignans exhibit a vast diversity in structure which leads to a well-established range of biological activities. Owing to these factors, lignans have proven to be a challenging and desirable synthetic target that has instigated the development of a number of different synthetic methods, advancing our collective knowledge toward the synthesis of complex and unique structures.

More generally, lignans are phenolic dimers possessing a 2,3-dibenzyl butane structure. Such compounds are known to exist as minor constituents of many plants, where they form the building blocks for the formation of lignin in the plant cell wall.

Structurally, lignans consist of two phenylpropane units linked together with β,β -bonds (Figure L-1). In some plants from the Magnoliales and Piperaceae family, some lignans have been identified that are linked together with other carbon-carbon bonds, which are referred to as neo-lignans (neolignans).

Figure L-1 Chemical structures of lignans.

Flaxseed contains by far the highest level of lignans, but vegetables, cereal brans, and legumes are also good sources, based on the amounts consumed in a high-fiber diet. Tea is also a good source of lignans.

See also: Flax and Flaxseed Oil, Lignin.

Lignin

Lignin is a complex biopolymer composed of different amounts of three monolignols, namely *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol. These propyl-phenol derivatives, which can be differentiated by their number of methoxy groups, include polar, hydroxyl, and carboxyl groups, which lead to the hydrophilic behavior in lignin. Lignin is a structural constituent of wood and (to a lesser extent) other plant tissues, which encrusts the walls and cements the cells together (Table L-4).

Table L-4 Amount (% w/w) of lignin common in various sources*.

Source	Lignin, % w/w
Bamboo	24-26
Cattle manure	2.7-5.7
Corn cobs	15
Corn stover	16-21
Grasses	10-30
Hardwood stem	18-25
Leaves	0
Newspaper	18-30
Nut shells	30-40
Paper	0-15
Rice straw	5.5
Softwood stem	25-35
Sugar cane bagasse	23-32
Sweet sorghum	11
Switchgrass	5-20
Waste papers from chemical pulps	5-10
Wheat straw	15-20

* The sources are listed alphabetically rather than in any other order.

See also: Table C-1.

An approximate classification of lignin derivatives is (i) softwood lignin, (ii) hardwood lignin, and (iii) grass lignin. There are several methods that can be used to separate the lignin, and therefore, various forms of lignin are available, such as milled wood lignin, dioxane lignin or enzymically liberated lignin, Kraft process lignin, and alkali lignin. Although the native lignin derivatives behave as an insoluble and three-dimensional chemical network, the isolated lignin derivatives often exhibit maximum solubility in solvents including dioxane, acetone, methyl cello-solve, tetrahydrofuran, dimethylformamide, and dimethyl sulfoxide.

The composition of lignin varies from species to species – as an example of composition from an aspen sample is carbon 63.4% w/w, hydrogen 5.9%, and oxygen 30% (by difference), mineral as 0.7% ash which corresponds to the approximate formula $(C_{31}H_{34}O_{11})_n$. As a biopolymer, lignin is unusual because of the heterogeneity and lack of a defined primary structure. Its most commonly noted function is the support through strengthening of wood. Structurally, lignin is a cross-linked polymer with a molecular mass in excess of 10,000, but the precise structure of lignin is unknown but it is believed to be a macromolecule, which consists of alkyl phenols and has a complex three-dimensional structure. Lignin is covalently linked with xylan derivatives in the case of hardwoods and with galactose-glucose-mannose units in softwoods. Lignin, together with hemicelluloses, acts as a cementing agent matrix of cellulose fibers in the woody structures of plants.

Lignin confers the hydrophobic properties reflecting the fact that it is based on aromatic ring systems. These three components are interwoven, and direct covalent linkages exist between the lignin and the hemicellulose. In chemical terms, the difference between hardwood and softwood is reflected in the composition of the constituent lignin. Chemically, hardwood lignin is primarily derived from sinapyl alcohol and coniferyl alcohol while softwood lignin is mainly derived from coniferyl alcohol.

Lignin is relatively hydrophobic and rich in aromatic subunits. The actual degree of polymerization is difficult to measure since the material is heterogeneous. The lignol derivatives that crosslink are of three main types, all derived from phenylpropane: 4-hydroxy-3-methoxy phenylpropane, 3,5-dimethoxy-4-hydroxy phenylpropane, and 4-hydroxy phenylpropane. The former tends to be more prevalent in conifers and the latter in hardwoods.

Different types of lignin have been described depending on the means of isolation. The three common monolignols presented below are (i) *trans*-coniferyl alcohol, (ii) *trans*-sinapyl alcohol, and (iii) *trans*-p-coumaryl alcohol. Thus, lignin can be defined as a polyphenolic material arising primarily from enzymic dehydrogenative polymerization of three phenylpropanoid units (p-hydroxy-cinnamyl alcohols). The proportions of the precursors in lignins vary with their botanical origin. Normal structural elements of softwood lignins are derived principally from *trans*-coniferyl alcohol (90%) with the remainder consisting mainly of *trans*-p-coumaryl alcohol. In contrast, hardwood lignins are mainly composed of *trans*-coniferyl alcohol and *trans*-sinapyl alcohol in varying ratios (about 50% for each alcohol).

Structural issues aside, lignin fills the spaces in the cell wall between cellulose, hemicellulose, and pectin components (structural acidic heteropolysaccharide derivatives contained in the primary cell walls of terrestrial plants), especially in vascular and support tissues. It is covalently linked to hemicellulose and therefore cross-links different plant polysaccharides, conferring mechanical strength to the cell wall and, by inference, to the whole plant.

Lignin plays a crucial part in conducting water in plant stems – the polysaccharide constituents of the plant cell are hydrophilic and thus permeable to water, whereas lignin is more hydrophobic and less permeable to water. The cross-linking of polysaccharides by lignin is an obstacle for water absorption to the cell wall and, thus, the presence of lignin makes it possible for the vascular tissue of the plant to conduct water efficiently.

Most lignin applications are based on technical lignins which are separated during pulping processes, and hydrolysis of lignin, which is obtained during wood acidic hydrolysis. The basic chemical phenylpropane units of lignin are bonded together by a set of linkages to form a complex matrix. This matrix comprises a variety of functional groups (such as hydroxyl, methoxyl, and carbonyl groups) which impart a high polarity to the lignin macromolecule.

The amount of extractable constituents is an important parameter which directly affects the heating value of wood (or, for that matter, any biomass). A high content of extractable constituents makes it desirable as fuel. The extractable constituents usually have low molecular weight and are soluble in neutral solvents. For example, terpene derivatives, lignan derivatives and other aromatic derivatives, fats, waxes, fatty acid derivatives and alcohol derivatives, turpentine, tannins, and flavonoids are categorized as extractable constituents. The contents of the extractable components vary among wood species, geographical site, and season and usually represent from between 3 to 10% by the weight of wood.

Lignin is a random polymer made up of phenyl propane units, where the phenol unit may be either a guaiacyl or syringyl unit. These units are bonded together in many ways, the most common of which are α -ether linkages or β -ether linkages. A variety of carbon-carbon linkages are also present, but are less common. The distribution of linkage in lignin is random because lignin formation is a free radical reaction that is not under enzymatic control. Lignin is highly resistant to chemical, enzymatic, or microbial hydrolysis due to extensive cross linking. Therefore, lignin is frequently removed simply to gain access to cellulose.

Lignin monomer units are similar to gasoline which has a high octane number, thus breaking the lignin molecules into monomers and removing the oxygen makes them useful as liquid fuels. The process for lignin conversion is mild hydrotreating to produce a mixture of phenolic and hydrocarbon materials, followed by reaction with methanol to produce methyl aryl ether.

The first step usually consists of two parts: hydrodeoxygenation (removal of oxygen and oxygen-containing groups from the phenol ring) and dealkylation (removal of ethyl or large side chains from the rings).

The major role is to carry out these reactions to remove the unwanted chains without carrying the reaction too far, which would lead to excessive consumption of hydrogen and produce saturated hydrocarbon derivatives, which are not as good octane enhancers as the aromatic compounds. Catalysts to carry out these reactions have dual functions. Metals such as molybdenum and molybdenum/nickel catalyze the deoxygenation, while the acidic alumina support promotes the carbon-carbon bond cleavage.

Although lignin chemicals have many applications such as in drilling mud, as binders for animal feed, and as the base for artificial vanilla, they have not been previously used as surfactants for oil recovery. Lignin chemicals can be used in two ways in chemical floods for enhanced oil recovery. In one method, lignosulfonates are blended with tallow amines and conventional petroleum sulfonates to form a unique mixture that costs approximately 40% less to use than chemicals made solely from petroleum or petroleum-based products. In the second method, lignin is reacted with hydrogen or carbon monoxide to form a new class of chemicals called lignin phenols. These phenols, because they are soluble in organic solvents, but not in water, are good candidates for further conversion to chemicals useful in enhanced oil recovery.

Lignocellulose

Lignocellulose (sometimes referred to as lignocellulosic biomass) has become a likely feedstock for the fuel and chemical industries in the event of an increase in oil and gas prices. Hemicellulose is a heteropolysaccharide built from different monosaccharides like pentoses and hexoses where xylose is predominant.

The features of lignocellulose that hinder enzyme access to the cellulose and hemicellulose include lignin content, hemicellulose content, acetyl content, cellulose crystallinity, degree of polymerization, and surface area and pore volume. Pretreatment of lignocellulose recalcitrance improves enzyme access by removing or altering lignin, removing hemicellulose, decrystallizing cellulose, and reducing the degree of polymerization in cellulose. The desirable characteristics of lignocellulose pretreatment process include preserving the cellulose and hemicellulose fractions, requiring minimal energy, and being effective on multiple lignocellulose feedstocks.

Lignocellulose is a complex matrix combining cellulose, hemicellulose, and lignin, along with a variable level of extractives. Cellulose is comprised of glucose, a six-carbon sugar, while hemicellulose contains both five- and six-carbon sugars, including glucose, galactose, mannose, arabinose, and xylose. The presence of cellulose and hemicellulose therefore makes lignocellulose a potential candidate for bioconversion. The ability of the bioconversion platform to isolate these components was initially limited, as the wood matrix is naturally resistant to decomposition.

By forming intramolecular and intermolecular hydrogen bonds between hydroxyl groups within the same cellulose chain and the surrounding cellulose chains, the chains tend to be arranged parallel and form a crystalline macromolecular structure. Bundles of linear cellulose chains (in the longitudinal direction) form a microfibril which is oriented in the cell wall structure. Cellulose is insoluble in most solvents and has a low accessibility to acid and enzymatic hydrolysis.

The ramified structure makes hemicellulose more resistant than cellulose to hydrolyzation – it is chemically bound to lignin, and it binds lignin and cellulose.

Limnology

Limnology is the study of fresh or saline waters contained within continental boundaries. Limnology and the closely related science of oceanography together cover all aquatic ecosystems. Limnology covers lakes, ponds, reservoirs, streams, rivers, wetlands, and estuaries, while oceanography covers the open sea. Limnology evolved into a distinct science only in the past two centuries, when improvements in microscopes, the invention of the silk plankton net,

and improvements in the thermometer combined to show that lakes are complex ecological systems with distinct structures. Today, limnology plays a major role in water use and distribution as well as in wildlife habitat protection. Limnologists work on lake and reservoir management, water pollution control, and stream and river protection, artificial wetland construction, and fish and wildlife enhancement.

Limnology is closely related to aquatic ecology and hydrobiology which involve the study of aquatic organisms and the interactions of these organisms with the abiotic (non-living) environment. While limnology has substantial overlap with freshwater-focused disciplines (such as freshwater biology), it also includes the study of inland salt lakes. A more recent sub-discipline of limnology is termed landscape limnology which involves studies, management, and the conservation of these ecosystems using a landscape perspective, by explicitly examining connections between an aquatic ecosystem and the related watershed. Recently, the need to understand global inland waters as part of the system of the Earth led to the creation of sub-discipline called global limnology which considers processes in inland waters on a global scale, like the role of inland aquatic ecosystems in global biogeochemical cycles.

Linseed oil

Linseed oil, also known as flaxseed oil or flax oil (in its edible form), is a colorless- to-yellowish oil obtained from the dried, ripened seeds of the flax lant (*Linum usitatissimum*). The oil is obtained by pressing which is sometimes followed by solvent extraction.

Linseed oil is a drying oil which can polymerize into a solid form. Owing to its polymer-forming properties, linseed oil can be used on its own or blended with combinations of other oils. Linseed oil is a triglyceride (Figure L-2), and it is distinctive for its unusually large amount of alpha-linolenic acid, which has a distinctive reaction with oxygen in air.

Figure L-2 Example of a complex triglycerides of the type found in linseed oil.

Specifically, the fatty acids in a typical linseed oil are of the following types: (i) the triply unsaturated α -linolenic acid, (ii) the saturated acids palmitic acid and stearic acid, (iii) the monounsaturated oleic acid, and (iv) the doubly unsaturated linoleic acid.

Lipids

Lipid derivatives are diverse in both their respective structures and functions. These diverse compounds that make up the lipid family are so grouped because they are insoluble in water (hydrophobic). They are also soluble in other organic solvents such as ether, acetone, and other lipids. Lipids serve a variety of important functions in living organisms and also act as chemical messengers, serve as valuable energy sources, provide insulation, and are the main components of membranes. Major lipid derivatives include the phospholipids derivatives.

Briefly, the phospholipids are a class of lipids that are a major component of all cell membranes. They can form lipid bilayers because of their amphiphilic characteristic. The structure of the phospholipid molecule generally consists of two hydrophobic fatty acid tails and a hydrophilic head consisting of a phosphate group. The two components are usually joined together by a glycerol ($\text{HOCH}_2\text{CHOHCH}_2\text{OH}$) molecule.

Liquefaction

Liquefaction is the conversion of a solid feedstock such as biomass into nearly mineral-free hydrocarbon liquids or low-melting solids by a process of direct or indirect hydrogenation at elevated temperatures and pressures and separation of liquid products from residue by either filtration or distillation or both. The production of liquid fuels from biomass is not new and has received considerable attention since the concept does represent alternate pathways to liquid fuels. In fact, the concept is often cited as a viable option for alleviating projected shortages of liquid fuels as well as offering some measure of energy independence for those countries with vast resources of biomass who are also net importers of crude oil.

The process options for biomass liquefaction can generally be divided into four categories: (i) pyrolysis, (ii) solvent extraction, (iii) catalytic liquefaction, and (iv) indirect liquefaction. The final category of direct liquefaction process employs the concept of catalytic liquefaction in which a suitable catalyst is used to add hydrogen to the feedstock. These processes usually require a liquid medium with the catalyst dispersed throughout or may even employ a fixed-bed reactor. On the other hand, the catalyst may also be dispersed within the feedstock whereupon the combined feedstock-catalyst system can be injected into the reactor. Many processes of this type have the advantage of eliminating the need for a hydrogen donor solvent (and the subsequent hydrogenation of the spent solvent), but there is still the need for an adequate supply of hydrogen. The nature of the process also virtually guarantees that the catalyst will be deactivated by the mineral matter in the feedstock as well as by coke lay-down during the process. Furthermore, in order to achieve the direct hydrogenation of the feedstock, the catalyst and the feedstock must be in intimate contact, but if this is not the case, process inefficiency is the general rule.

Liquid Absorption Processes

Liquid absorption processes evolved from dry box processes. They are based on the same reactions as the dry box methods, using a metal oxide to react with hydrogen sulfide to form a metal sulfide compound. These liquid processes were developed to facilitate simple and rapid change out of the media while also enabling the development of continuous processes. They are generally composed of a slurry of active metal oxides suspended in water. The primary metal oxides used are iron oxide and zinc oxide.

Liquid absorption processes (which usually employ temperatures below 50°C , 120°F) are classified either as *physical solvent processes* or *chemical solvent processes*. The former processes employ an organic solvent, and absorption is enhanced by low temperatures, or high pressure, or both. Regeneration of the solvent is often accomplished readily. In chemical solvent processes, absorption of the acid gases is achieved mainly by use of alkaline solutions such as amines or carbonates. Regeneration (desorption) can be achieved by use of reduced pressures and/or high temperatures, whereby the acid gases are stripped from the solvent.

Liquid Biofuels

Fossil fuels applications are linked with current widely held environmental issues, and the decline of fossil fuel resources with environmental penalties has compelled for substitutes and usage of renewable biofuel as energy sources; it has gained a significant importance in last three decades, and the production of fuels from biological resources is proving to be an ecologically viable and sustainable option.

Liquid biofuels include liquid fuels – such as biodiesel and bioethanol – that are produced from various types of biomass, several kinds of biowastes, and agricultural residues, is an ecologically viable and sustainable option. Currently, the most widely used liquid biofuels for transport are ethanol and biodiesel. Ethanol is a type of alcohol that can be produced using any feedstock containing significant amounts of sugar, such as sugar cane or sugar beet, or starch, such as maize and wheat.

There are various ways of producing biofuels, but the processes generally use chemical reactions, fermentation, and heat to break down the starch derivatives, sugar derivatives, as well as other plant-based chemicals. The resulting products are then refined to produce a fuel that cars or other vehicles can use.

See also: Biofuels – Bioalcohol, Biodiesel, Ethanol, Liquid, Liquid Fuels.

Liquid Fuels

Liquid fuels are combustible or energy-generating molecules that can be harnessed to create mechanical energy. It is the fumes of liquid fuels that are flammable instead of the fluid. Most liquid fuels in widespread use are derived from fossil fuel sources, but there are several types derived from non-fossil fuel sources – these are hydrogen, methanol, ethanol, and biodiesel that are derived from non-fossil fuel sources which are also categorized as a liquid fuel.

Biofuel is a generic name for gaseous, liquid, or solid fuels that are not derived from fossil fuels or contain a proportion of non-fossil fuel. For the purposes of this text, the term alternate fuels is used to represent those fuels that are produced from plant sources as well as from other sources such as the organic constituents (predominantly biological in nature) municipal and industrial waste. Thus, biofuels are *bio-materials* that are produced made from renewable biological sources which are now contemplated as grown specifically for the purpose of providing useful heat upon combustion. Biofuels are produced from sources such as: corn, soybeans, flaxseed, rapeseed, sugarcane, palm oil, sugar beet raw sewage, food scraps, animal parts, and rice.

Biofuels are fuels derived from plant materials – and are entering the market, driven by factors such as oil price spikes and the need for increased energy security. Examples of solid biofuels include wood, sawdust, grass cuttings, domestic refuse, charcoal, agricultural waste, non-food energy crops, and dried manure. Biofuels are also known as non-conventional fuels or alternative fuels. Alternative fuels can be classified as any fuel that is not derived from conventional sources like natural gas, crude oil, and coal.

Liquid Fuels from Biomass

Generally, liquid fuels are those fuels (often but not always hydrocarbon derivatives) which flow readily under ambient conditions. Liquid fuels from biomass represent a different class of chemicals.

Alcohols are oxygenate fuels insofar as the alcohol molecule has one or more oxygen, which decreases to the combustion heat. Practically, any of the organic molecules of the alcohol family can be used as a fuel. The alcohols can be used for motor fuels are methanol (CH_3OH), ethanol ($\text{C}_2\text{H}_5\text{OH}$), propanol ($\text{C}_3\text{H}_7\text{OH}$), and butanol ($\text{C}_4\text{H}_9\text{OH}$). However, only methanol and ethanol fuels are technically and economically suitable for internal combustion engines.

Ethanol (ethyl alcohol, $\text{CH}_3\text{CH}_2\text{OH}$), also referred to as bioethanol, is a clear, colorless liquid with a characteristic, agreeable odor. Currently, the production of ethanol by fermentation of corn-derived carbohydrates is the main technology used to produce liquid fuels from biomass resources. Furthermore, among different biofuels, suitable for

application in transport, bioethanol and biodiesel seem to be the most feasible ones at present. The key advantage of bioethanol and biodiesel is that they can be mixed with conventional petrol and diesel respectively, which allows using the same handling and distribution infrastructure. Another important strong point of bioethanol and biodiesel is that when they are mixed at low concentrations ($\leq 10\%$ bioethanol in petrol and $\leq 20\%$ biodiesel in diesel), no engine modifications are necessary.

Ethanol can be blended with gasoline to create E85, a blend of 85% ethanol and 15% gasoline. E85 blends with even higher concentrations of ethanol, E95; pure bioethanol (E100-fuel) has been used mainly in Brazil. More widespread practice has been to add up to 20% to gasoline (E20-fuel or gasohol) to avoid engine changes.

Ethanol has a higher octane number (108), broader flammability limits, higher flame speeds, and higher heats of vaporization than gasoline. These properties allow for a higher compression ratio, shorter burn time, and leaner burn engine, which lead to theoretical efficiency advantages over gasoline in an internal combustion engine.

On the other hand, the disadvantages of ethanol include its lower energy density than gasoline, its corrosiveness, low flame luminosity, lower vapor pressure, miscibility with water, and toxicity to ecosystems.

Ethanol from cellulosic biomass materials (such as agricultural residues, trees, and grasses) is made by first using pretreatment and hydrolysis processes to extract sugars, followed by fermentation of the sugars. Although producing ethanol from cellulosic biomass is currently more costly than producing ethanol from starch crops, several countries (including the United States) have launched biofuels initiatives with the objective of the economic production of ethanol from bio-sources. Researchers are working to improve the efficiency and economics of the cellulosic bioethanol production process.

In the process, the carbohydrate from the biomass into sugar; this is converted to ethanol in a fermentation process that is similar to the process for brewing beer. Typical feedstocks for the process are sugar beets and from molasses and yield are on the order of 72.5 liters of ethanol per ton of sugar cane. Modern crops yield 60 tons of sugar cane per hectare of land. Production of ethanol from biomass is one way to reduce both the consumption of crude oil and environmental pollution. Domestic production and use of ethanol for fuel can decrease dependence on foreign oil, reduce trade deficits, create jobs in rural areas, reduce air pollution, and reduce global climate change carbon dioxide buildup.

Ethanol can also be produced by synthesis from the chemical compound ethylene, which is derived from crude oil or natural gas, or by the fermentation of carbohydrates.

Methanol (methyl alcohol, wood alcohol, CH_3OH) is mainly manufactured from natural gas, but biomass can also be gasified to methanol. Methanol can be made with any renewable resource containing carbon such as seaweed, waste wood, and garbage. Methanol is stored and handled like gasoline because it is produced as a liquid. Methanol is currently made from natural gas, but it can also be made from a wide range of renewable biomass sources, such as wood or waste paper.

In comparison to gasoline, ethanol contains 35% oxygen by weight; gasoline contains none. The presence of the oxygen promotes more complete combustion which results in fewer tailpipe emissions. Compared to the combustion of gasoline, the combustion of ethanol substantially reduces the emission of carbon monoxide, volatile organic compounds, particulate matter, and greenhouse gases. However, a unit of ethanol contains approximately 32% less energy than a liter of gasoline. One of the best qualities of ethanol is its octane rating.

Methanol can be used as one possible replacement for conventional motor fuels and has favorable properties. Methanol has been seen as a possible large volume motor fuel substitute at various times during gasoline shortages. It was often used in the early part of the century to power automobiles before inexpensive gasoline was widely introduced. Methanol is poisonous and burns with an invisible flame. Methanol has just like ethyl alcohol a high octane rating, and hence an Otto engine is preferable. If an ignition booster is used, methanol can be used in a diesel engine.

Methanol also offers important emissions benefits compared with gasoline. It can reduce hydrocarbon emissions by 30 to 40% with M85 and up to 80% with M100 fuels. Methanol costs less than gasoline, but has lower energy content. Taking this into account, costs for methanol in a conventional vehicle are slightly higher than those for gasoline. When used in fuel cells, which are considerably more efficient, fuel costs will be lower. Three important points of comparison are emissions, fuel economy, and octane quality.

Methanol and methanol blends have higher octane ratings than gasoline, which reduces engine knock and can produce in higher engine efficiency. The higher octane also gives methanol-fueled vehicles more power and quicker

acceleration. A higher octane rating allows certain engine design parameters, such as compression ratio, and valve timing, to be altered in such ways that fuel economy and power are increased.

E100-fueled and M100-fueled vehicles have difficulty starting in cold weather, but this is not a problem for E85 and M85 vehicles because of the presence of gasoline.

P-Series fuels are a unique blend of natural gas liquids, ethanol, and hydrocarbon derivatives methyl tetrahydrofuran ($\text{CH}_3\text{C}_4\text{H}_7\text{O}$) and are a biomass-derived product. These fuels are clear, colorless liquid blends (octane number: 89 to 93) that are formulated to be used in flexible fuel vehicles. Like gasoline, low vapor pressure formulations are produced to prevent excessive evaporation during summer and high vapor pressure formulations are used for easy starting in the winter. Also, these fuels are at least 60% non-petroleum and the majority of the components that make up P-series fuels come from domestically produced renewable resources.

The P-Series fuels provide significant emissions benefits over reformulated gasoline. Each unit of P-series fuel emits approximately 50% less carbon dioxide, 35 % less hydrocarbon derivatives, and 15% less carbon monoxide than gasoline. The fuel also has 40% less ozone forming potential. The other gasoline-substitute ether, MTBE (methanol tertiary butyl ether), is a petroleum-derived product and is made from isobutene [$(\text{CH}_3)_2\text{CH}=\text{CH}_2$ and methanol]. The P-series fuel emissions are generally below those for reformulated gasoline and are well below federal emissions standards. P-series fuels join the list of alternatives to gasoline that includes ethanol (E85), methanol (M85), natural gas, propane, and electricity.

Biodiesel is the generic name for fuels obtained by esterification of vegetable oil. The esterification can be done either by methanol or by ethanol. Biodiesel can be used in a diesel engine without modification and is a clean burning alternative fuel produced from domestic, renewable resources. The fuel is a mixture of fatty acid alkyl esters made from vegetable oils, animal fats, or recycled greases. Where available, biodiesel can be used in compression-ignition (diesel) engines in its pure form with little or no modifications.

Biodiesel is biodegradable, nontoxic, and essentially free of sulfur and aromatics. It is usually used as a petroleum diesel additive to reduce levels of particulates, carbon monoxide, hydrocarbon derivatives, and air toxics from diesel-powered vehicles. When used as an additive, the resulting diesel fuel may be called B5, B10, or B20, representing the percentage of the biodiesel that is blended with petroleum diesel.

Biodiesel is produced through a process in which organically derived oils are combined with alcohol (ethanol or methanol) in the presence of a catalyst to form the ethyl or methyl ester. The biomass-derived ethyl or methyl esters can be blended with conventional diesel fuel or used as a neat fuel (100% biodiesel). Biodiesel can be made from any vegetable oil, animal fats, waste vegetable oils, or microalgae oils. Soybeans and Canola (rapeseed) oils are the most common vegetable oils used currently.

Biodiesel is usually made from soybean oil or recycled cooking oils. Animal fats, other vegetable oils, and other recycled oils can also be used to produce biodiesel, depending on their availability.

The production of biodiesel from vegetable oil represents another means of producing liquid fuels from biomass, and one which is growing rapidly in commercial importance. Commercially, biodiesel is produced from vegetable oils, including rapeseed, sunflower and soybean oil, and animal fats. These oils and fats are typically composed of C_{14} to C_{20} fatty acid triglycerides (constituting approximately 90 to 95% by weight of the oil). In order to produce a fuel that is suitable for use in diesel engines, these triglycerides are converted to the respective alkyl esters and glycerol by base-catalyzed transesterification with short chain alcohols (generally methanol).

Thus, for every 10 lbs. of biodiesel produced, approximately 1 lb. of glycerol is formed. Glycerol finds application in a wide range of industries (cosmetics, pharmaceuticals, as a plasticizer, etc.), although as biodiesel production grows, new uses will have to be developed to avoid a surplus of glycerol.

Fuel-grade biodiesel must be produced to strict industry specifications (ASTM D6751) in order to ensure proper performance. Biodiesel is the only alternative fuel to have fully completed the health effects testing requirements of the 1990 Clean Air Act Amendments and biodiesel that meets ASTM D6751 and is legally registered with the Environmental Protection Agency is a legal motor fuel for sale and distribution. Raw vegetable oil cannot meet biodiesel fuel specifications; therefore, it is not registered with the EPA and it is not a legal motor fuel.

A totally different process than that used for biodiesel production can be used to convert biomass into a type of fuel similar to diesel which is known as bio-oil. The process (fast pyrolysis, flash pyrolysis) occurs when solid fuels are heated at temperatures between 350 and 500°C (660 and 930°F) for a short period of time (<2 seconds). The bio-oils currently produced are suitable for use in boilers for electricity generation.

In another process, the feedstock is fed into a fluidized bed (at 450 to 500°C, 845 to 930°F) and the feedstock flashes and vaporizes. The resulting vapors pass into a cyclone where solid particles, char, are extracted. The gas from the cyclone enters a quench tower where they are quickly cooled by heat transfer using bio-oil already made in the process. The bio-oil condenses into a product receiver, and any non-condensable gases are returned to the reactor to maintain process heating. The entire reaction from injection to quenching takes only two seconds.

Liquid Fuels From Waste

Using ethanol as the example, numerous waste streams could be exploited for ethanol production. They are often inexpensive to obtain, and in many instances, they have a negative value attributable to current disposal costs. Some principal waste streams currently under consideration include mixed paper from municipal solid waste, cellulosic fiber fines from recycled paper mills, as well as various bio-feedstocks.

However, each waste stream has its own unique characteristics, and they generally vary from one source or time to another. Therefore, ethanol or, for that matter, the production of liquid fuels from waste streams is not only feedstock dependent but is also process dependent.

Using the term loosely, the standard way of preparing hydrocarbon liquid fuels from carbonaceous material is to (i) gasify the feedstock to produce synthesis gas and (ii) convert the synthesis gas by the Fischer-Tropsch reaction to hydrocarbon derivatives.

Synthesis gas (syngas) is the name given to a gas mixture that contains varying amounts of carbon monoxide and hydrogen generated by the gasification of a carbonaceous fuel to a gaseous product with a heating value. Examples include (i) steam reforming of natural gas or liquid hydrocarbon derivatives to produce hydrogen and (ii) waste-to-energy gasification processes.

Synthesis gas consists primarily of (predominantly) carbon monoxide and hydrogen and has less than half the energy density of natural gas. Synthesis gas is combustible and often used as a fuel source or as an intermediate for the production of other chemicals. Synthesis gas for use as a fuel is most often produced by gasification of coal or municipal waste mainly by the following paths:

When used as an intermediate in the large scale, industrial synthesis of hydrogen and ammonia, it is also produced from natural gas (via the steam reforming reaction) as follows:

The Fischer-Tropsch synthesis is, in principle, a carbon chain building process, where methylene groups are attached to the carbon chain. The actual reactions that occur have been, and remain, a matter of controversy, as it has been the last century since 1930s.

The initial reactants in the above reaction (i.e., CO and H₂) can be produced by other reactions such as the partial combustion of a hydrocarbon derivative:

For example (when $n=1$), methane (in the case of gas-to-liquids applications):

Or by the gasification of any carbonaceous source, such as biomass and, in the current context, carbonaceous waste:

The energy needed for this endothermic reaction is usually provided by (exothermic) combustion with air or oxygen:

A modification of this concept involves the proposed addition of addition of hydrogen from a carbon-free energy source, such as solar or nuclear power, during the gasification step. The theoretical concept is a hybrid process insofar as liquid hydrocarbon fuels are proposed to be produced from biomass wherein biomass is the carbon source and hydrogen is supplied from carbon-free energy. Modeling of this biomass-to-liquids process indicates that the concept has the potential to provide the transportation sector for the foreseeable future, using the existing infrastructure.

In addition, although not mentioned because the concept is modeled on the complete gasification of the feedstock, the addition of hydrogen will not only suppress the formation of carbon dioxide but also the formation of other by-products thereby increasing the efficiency of the process. The presence of hydrogen will also reduce the amount of char and tarry by-products which is in complete agreement with the observed beneficial effect of hydroprocesses in petroleum refineries which has been known for decades. The hydrogen and energy balance may be even better if water (also produced during gasification) could be used as the hydrogen source.

The pyrolysis of waste tires is also a source of liquid fuels; the process by which this is achieved is often called thermal depolymerization. This term, however, is more a term of convenience since it is rare that depolymerization, in the true scientific sense, actually occurs.

Thermal depolymerization (TDP) is a term that is used to describe the reduction of complex organic materials into lower-molecular-weight products. Nevertheless, in this context, thermal cracking and catalytic cracking as used in the petroleum industry are examples of thermal depolymerization. The feedstocks for such processes may also include non-oil-based waste products, such as old tires, offal, wood, and plastic. However, the so-called thermal depolymerization process does not in any way mimic the natural geological processes thought to be involved in the production of fossil fuels, such as petroleum and natural gas.

In the thermal depolymerization process, conversion efficiencies can be high but is feedstock dependent. Quantifying the potential amount of product (e.g., biodiesel) can be done on a feedstock carbon compared to product carbon basis, but such estimates are only approximate.

Quantifying the amount of oil which could be produced from tire pyrolysis can be done in a similar manner to quantifying the amount of biodiesel produced from waste vegetable oil. It is simply a case of equating the amount of waste product available to the production yields. In the case of tire pyrolysis, the number of used tires produced each year is well documented. What is less certain, however, is the amount of suitable road transport oil that can be yielded from the pyrolysis process itself.

Another source of waste for the production of liquid fuels is waste cooking oil; usually, biodiesel is the desired product. In fact, waste cooking oil is a valuable asset for conversion to liquid fuels and the quantity of biodiesel which could be produced from waste cooking oil can be quantified in a manner similar to that of biodiesel produced direct from agriculture. The only difference is that rather than calculating crop yields, it is necessary to quantify the amount of waste oil available.

Biodiesel is a light-to-dark-yellow liquid that is immiscible with water and has a high boiling point and low vapor pressure. Typical methyl ester biodiesel has a flash point on the order of approximately 150°C (300°F), making it non-flammable. Biodiesel has a density of 0.88 g/cm³. Biodiesel has a viscosity similar to diesel derived from crude

oil (sometimes referred to as petrodiesel to differentiate the different forms of diesel) and can be used as an additive in formulations of diesel to increase the lubricity of pure ultra-low sulfur diesel (ULSD) fuel. Much of the world uses a system known as the “B” factor to state the amount of biodiesel in any fuel mix, in contrast to the “BA” or “E” system used for blends of diesel fuel with ethanol. For example, fuel containing 20% biodiesel is labeled B20 whereas pure biodiesel is referred to as B100.

Biodiesel is a renewable fuel that can be manufactured from algae, vegetable oils, animal fats, or recycled restaurant greases; it can be produced locally in most countries. It is safe, biodegradable, and reduces air pollutants, such as particulates, carbon monoxide, and hydrocarbon derivatives. Blends of 20% biodiesel with 80% petroleum diesel (B20) can generally be used in unmodified diesel engines. Biodiesel can also be used in its pure form (B100), but may require certain engine modifications to avoid maintenance and performance problems.

Biodiesel is an alternative to petroleum-based diesel, but it is produced from biodegradable materials and can be used as fuel in diesel engines. It can also be used in boilers or furnaces designed to use heating oil or in oil-fueled lighting equipment or used neat (100% biodiesel), or it can be blended with petroleum diesel.

Biodiesel is made by chemically reacting vegetable oil or animal fat (or combinations of oils and fats) with alcohol (usually nearly pure methanol or ethanol) and a catalyst (sodium hydroxide). The chemical reaction converts constituents of the vegetable oil into an ester (biodiesel fuel) and glycerol. Since the biodiesel is less dense than the glycerol, it floats on top of the glycerol and may be pumped off, or the glycerol can be drained off the bottom. The fuel can then be filtered and used in heating or lighting applications. It is possible to use the product in diesel engines without further processing, but caution is advised because of the potential for engine damage, and it is recommended that impurities (unreacted alcohol and sodium hydroxide) are removed by washing.

Almost any variety of oil or grease (from new food-grade vegetable oil to used cooking oil or trap grease to wastewater treatment-plant grease) can be converted and turned into biodiesel. However, the amounts of reactants (oil, methanol, and sodium hydroxide) vary to some degree, depending on what oil is used. The amount of methanol and sodium hydroxide must be sufficient to react with the vegetable oil, but excessive amounts of these reactants should not be used. Just as an engine requires excess air to be sure that all the fuel burns, it takes excess methanol to be sure all of the oil reacts.

The chemistry of biodiesel production is known as transesterification insofar as the process involves reaction of a glyceride-containing plant oil with a short chain alcohol such as methanol or ethanol. The process can be represented simply as:

Vegetable oil → transesterification/methanol → glycerol/methanol + crude biodiesel
 Vegetable oil → transesterification/ethanol → glycerol/ethanol + crude biodiesel
 Glycerol/methanol → refining → glycerol + methanol
 Glycerol/ethanol → refining → glycerol + ethanol
 Crude biodiesel → biodiesel

Animal and plant fats and oils are typically made of triglyceride derivatives which are esters of free fatty acid derivatives with the trihydric alcohol, glycerol. In the transesterification reaction, the alcohol is deprotonated with a base to make it a stronger nucleophile. Commonly, ethanol or methanol is used. Usually, this reaction will proceed either slowly or not at all. Heat, as well as an acid or base, is used to help the reaction proceed more quickly.

Almost all biodiesel is produced using the base-catalyzed technique as it is the most economical process requiring only low temperatures and pressures and producing over 98% conversion yield (provided the starting oil is low in moisture and free fatty acids).

The major steps required to synthesize biodiesel are (i) purification, (ii) neutralization, (iii) transesterification, and (iv) workup.

Purification is required if waste vegetable oil is used, it is filtered to remove dirt, charred food, and other non-oil material often found. Water is removed because its presence causes the triglycerides to hydrolyze to give salts of the fatty acids instead of undergoing transesterification to give biodiesel. The crude oil may be stirred with a drying agent such as magnesium sulfate to remove the water in the form of water of crystallization. The drying agent can be separated by decanting or by filtration, but the viscosity of the oil may not allow the drying agent to mix thoroughly.

Neutralization of free fatty acids in which a sample of the cleaned oil is titrated against a standard solution of base in order to determine the concentration of free fatty acids (RCOOH) present in the waste vegetable oil sample. The quantity (in moles) of base required to neutralize the acid is then calculated.

Transesterification in which while adding the base, a slight excess is factored in to provide the catalyst for the transesterification. The calculated quantity of base (usually sodium hydroxide) is added slowly to the alcohol, and it is stirred until it dissolves. Sufficient alcohol is added to make up three full equivalents of the triglyceride, and an excess is added to drive the reaction to completion. The solution of sodium hydroxide in the alcohol is then added to a warm solution of the waste oil, and the mixture is heated (typically 50°C) for several hours (4 to 8 typically) to allow the transesterification to proceed. A condenser may be used to prevent the evaporative losses of the alcohol. Care must be taken not to create a closed system which can explode.

Workup occurs when the reaction is complete. The glycerol should sink, but when ethanol is used, it is reported that an emulsion often forms. This emulsion can be broken by standing, centrifugation, or the addition of a low-boiling (easily removed) non-polar solvent, decanting, and distilling. The top layer, a mixture of biodiesel and alcohol, is decanted. The excess alcohol can be distilled off, or it can be extracted with water. If the latter, the biodiesel should be dried by distillation or with a drying agent.

The overall process consists of a thermo-chemical conversion of synthesis gas which is then converted to higher-molecular-weight alcohols by a catalytic process after which high purity ethanol is separated by distillation. The process is similar to modern-day methanol and gas-to-liquids processes. The key differentiating factors are the catalysts and their operating parameters.

Liquid Fuels from Wood

Wood can be used to make both liquid and gaseous fuels. When wood is heated in the absence of air, or with a reduced air supply, it is possible to produce a liquid fuel which can be used in a similar way to conventional oil fuels. It can be used to run internal combustion engines in vehicles or generators. The gas produced from wood is a mixture of hydrogen and carbon monoxide (synthesis gas) which is similar to the coal gas which was made before the arrival of natural gas from the North Sea. This wood gas can be used in internal combustion engines or in gas turbines which can be used to power generators. Although the liquid fuels are rarely produced from wood at present, wood gas is important in other countries for producing electricity in more remote areas.

Processes for making liquid fuels from wood have been understood and available for longer than such fuels have been used in vehicles for transportation. However, the economics of liquid fuels from wood as compared to liquid fuels from fossil fuels have been unfavorable. Nevertheless, the recent phenomenal increases in the cost of gasoline and diesel fuel, that seem to bear little relationship to the increases in petroleum process, has caused a renewed interest in liquid fuels from sources other than petroleum. Wood is a fuel source of interest!

The three approaches that are most promising for making liquid fuels from wood are methanol, ethanol, and diesel fuel, but other liquid fuels from wood are possible. Methanol was the first fuel from wood and is often called wood alcohol. Ethanol has been the focus of research at the Forest Products Laboratory. There has been little attention to diesel fuel from wood, although there has been some research on production from synthesis gas and through utilization of extractable materials from wood.

Liquid fuels that could be suitable for use in transportation vehicles have been made from wood for a long time. Methanol was commonly called wood alcohol, and this term is still used. Cellulose which is the largest wood component could be dissolved in concentrated acid solutions and converted to sugar, a precursor for making ethanol. A dilute sulfuric acid hydrolysis process was used to make ethanol during World War I, and wood hydrolysis received considerable attention in Europe during the period between the World Wars I and II. Wood hydrolysis plants continue to operate in Russia.

However, methanol and ethanol are not the only transportation fuels that might be made from wood. A number of possibilities exist for producing alternatives. The most promising biomass fuels, and closest to being competitive in current markets without subsidy, are (i) ethanol, (ii) methanol, (iii) ethyl-t-butyl ether, and (iv) methyl-t-butyl ether.

Other candidates include isopropyl alcohol, sec-butyl alcohol, t-butyl alcohol, mixed alcohols, and t-amyl methyl ether.

Ethanol or grain alcohol is not restricted to grain as a feedstock. It can be produced from other agricultural crops and lingo-cellulose compounds such as wood. It has often been advocated as a motor fuel, and has been used frequently in times of gasoline scarcity.

Another possibility for oxygenated fuels is methanol. Methanol could conceivably be made from grain, but its most common source is natural gas. Use of natural gas is better for reducing carbon dioxide production in comparison to other fossil fuels, but use of renewable fuels instead of natural gas would be still better. It can be made from coal or wood with more difficulty and lower efficiency than from natural gas.

High octane rating is characteristic of all oxygenated fuels, including ethanol, methanol, ethyl-t-butyl ether, and methyl-t-butyl ether. A large part of the success of ethanol from grain in the current United States mix of motor fuels is its ability to raise octane rating in a 10% mixture of ethanol with 90% gasoline. However, it is the recent phenomenal growth in the use of methyl-t-butyl-ether (MTBE) as an octane enhancer that has captured worldwide attention. MTBE is made by reacting isobutylene with methanol. Ethyl-t-butyl ether (ETBE) is made by using ethanol instead of methanol. Thus, either ethanol or methanol from either grain or wood could be a factor in making t-butyl ether octane enhancers. The characteristics of ethers are generally closer to those of gasoline than those of alcohols.

Ethers are benign in their effect on fuel system materials and are miscible in gasoline; therefore, they are not subject to phase separation in the presence of water, as are methanol and ethanol. Ethers are non-polar. They are of low volatility and thus give low evaporative emissions.

Alternative fuels from wood, as well as grain, have a potential for being competitive with gasoline and diesel motor fuels from petroleum, even without subsidization. Currently, ethanol from grain and a slight amount from wood are competing, but only with a large Federal and some State subsidies. However, environmental and octane-enhancing benefits of ethanol and other oxygenated fuels that may be produced from grain and wood may make them worth more than comparisons on fuel value alone would indicate.

Diesel fuel or gasoline from wood are possibilities through a number of approaches. The one that appears simplest is to use an exudation or gum from a tropical wood species, *Copaifera*, which is said to be directly combustible in a diesel engine. The Fischer-Tropsch pyrolysis process, used successfully for converting coal to synthesis gas in South Africa, could also be used to make synthesis gas from wood. Synthesis gas could then be used to make gasoline or diesel fuel. Or methanol could be produced from wood and then, by a catalyzed reaction known as the Mobil process, be transformed to gasoline.

Although, ideally, there should be additional pilot testing for any process to produce ethanol or methanol from wood commercially, technology for ethanol production has been developed and subjected to some pilot testing. The technology is available for fairly rapid implementation, should the need for alternative fuels become pressing as the result of another global petroleum emergency. Depending on feedstock costs and other variables, ethanol from wood might or might not be able to compete with ethanol from corn. Another important consideration is production and marketing of by-products such as high fructose corn syrup and distillers dry grains from corn and molasses and/or furfural from wood. The two-stage, dilute sulfuric acid hydrolysis process is a possibility for commercial application in producing ethanol from low-grade hardwoods.

In the two-stage hydrolysis process, for every 100 kg of oven-dry wood feedstock, approximately 20 kg carbohydrates suitable for processing to ethanol are obtained from the second stage. There are more carbohydrates derived from the first stage, approximately 24.9 kg, but many of these first-stage carbohydrates are not necessarily fermentable to ethanol.

Ethanol is a possibility if xylose can be fermented to ethanol economically. Fermentation of the xylose and glucose from the first stage could result in almost doubling the ethanol production as compared to only fermenting the glucose from the second stage. Other possible products from the first-stage carbohydrates are single-cell protein, furfural, and feed molasses.

Methanol was once produced from wood as a by-product of charcoal manufacture, but overall yields were low. To produce methanol from wood with a significantly higher yield would require production of synthesis gas in a process similar to that used for production of methanol from coal. Such processes for gasifying wood are less fully developed than the two-stage hydrolysis process for production of ethanol. Another consideration in producing liquid fuels from wood is the amount of wood available to manufacture the fuels.

For converting wood to liquid fuel, the most optimistic assumption normally used is that wood could be converted to liquid fuel in the ratio of BTU in liquid fuel/BTU in wood = 0.5. At least in the short run, it would be difficult to find more than 100 million dry tons of wood per year (1.7 Quads equivalent) for this purpose. This would calculate to be a maximum of 13 billion gallons per year if the output was methanol, and the energy content of a ton of dry wood is assumed to be 17 million BTU. On the order of 11.5 billion gallons per year would be needed if methanol were added to gasoline at the rate of 10% methanol to 90% gasoline.

Projections of wood use for energy to 2010 are modest. Currently, 2.7 Quads of energy are produced from wood. Projections of the total for 2010 are approximately 4.0 Quads. This does not provide for a total growth of even 1.7 Quads. However, if we really want to get serious approximately doing something to deter atmospheric CO₂ accumulation, the availability of wood for energy, including solid as well as liquid fuel, could be increased, up to 10 Quads per year might be very realistic. This runs counter to decreased usage of wood for all purposes, particularly from the National forests, to provide more wilderness, habitat for threatened and endangered species, clean water, and other environmental considerations. However, it must be remembered that, in some cases, more harvesting and clean-up of residues is needed to increase the vigor of forest growth, to protect the forest against wildfire, and to prepare the soil for new growth.

Liquid Fuels – Biodiesel

Among the liquid biomass fuels, biodiesel (vegetable oil ester) is noteworthy for its similarity to crude oil-derived diesel fuel, apart from its negligible sulfur and ash content. Bioethanol has only approximately 70% the heating value of crude oil distillates such as gasoline, but its sulfur and ash contents are also low. Both of these liquid fuels have lower vapor pressure and flammability than their crude oil-based competitors – an advantage in some cases (e.g., use in confined spaces such as mines) but a disadvantage in others (e.g., engine starting at cold temperatures).

Currently, the production of ethanol by fermentation of corn-derived carbohydrates is the main technology used to produce liquid fuels from biomass resources. Furthermore, among different biofuels, suitable for application in transport, bioethanol and biodiesel seem to be the most feasible ones at present. The key advantage of bioethanol and biodiesel is that they can be mixed with conventional gasoline and diesel, respectively, which allows using the same handling and distribution infrastructure. Another important strong point of bioethanol and biodiesel is that when they are mixed at low concentrations ($\leq 10\%$ bioethanol in gasoline and $\leq 20\%$ biodiesel in diesel), no engine modifications are necessary.

Alternatively, biomass can be converted into fuels and chemicals indirectly (by gasification to synthesis gas followed by catalytic conversion to liquid fuels) or directly to a liquid product by thermochemical means. Direct thermochemical conversion processes include pyrolysis, liquefaction, and solvolysis. Thermochemical treatment of biomass to produce hydrocarbon derivatives has been studied since the 1930s, and while relatively simple to perform, typically such processes are non-selective, producing a wide range of products.

The production of biodiesel from vegetable oil represents another means of producing liquid fuels from biomass, and one which is growing rapidly in commercial importance. Commercially, biodiesel is produced from vegetable oils, including rapeseed, sunflower and soybean oil, and animal fats. These oils and fats are typically composed of C₁₄ to -C₂₀ fatty acid triglycerides (constituting approximately 90 to 95% by weight of the oil). In order to produce a fuel that is suitable for use in diesel engines, these triglycerides are converted to the respective alkyl esters and glycerol by base-catalyzed transesterification with short chain alcohols (generally methanol).

Thus, for every 10 units of biodiesel produced, approximately 1 unit of glycerol (HOCH₂CHOHCH₂OH) is formed. Glycerol finds application in a wide range of industries (such as cosmetics, pharmaceuticals, and plasticizers).

Liquid Fuels – Ethanol

Ethanol is the predominant fuel produced from crops and has been used as fuel in the United States since at least 1908. Although early efforts to sustain an ethanol program failed, oil supply disruptions in the Middle East and

environmental concerns over the use of lead as a gasoline octane booster renewed interest in ethanol in the late 1970s. At present, extending the volume of conventional gasoline is a significant end use for ethanol, as is its use as an oxygenate. To succeed in these markets, the cost of ethanol must be close to the wholesale price of gasoline, currently made possible by the federal ethanol subsidy. However, in order for ethanol to compete on its own merits, the cost of producing it must be reduced substantially.

The production of ethanol from corn is a mature technology that holds much potential. Substantial cost reductions may be possible, however, if cellulose-based feedstocks are used instead of corn. Producers are experimenting with units equipped to convert cellulose-based feedstocks, using sulfuric acid to break down cellulose and hemicellulose into fermentable sugar. Although the process is expensive at present, advances in biotechnology could decrease conversion costs substantially. The feed for all ethanol fermentations is sugar – traditionally a hexose (a six-carbon or “C6” sugar) such as those present naturally in sugar cane, sugar beet, and molasses. Sugar for fermentation can also be recovered from starch, which is actually a polymer of hexose sugars (*polysaccharide*).

Biomass, in the form of wood and agricultural residues such as wheat straw, is viewed as a low-cost alternative feed to sugar and starch. It is also potentially available in far greater quantities than sugar and starch feeds. As such, it receives significant attention as a feed material for ethanol production. Like starch, wood and agricultural residues contain polysaccharides. However, unlike starch, while the cellulose fraction of biomass is principally a polymer of easily fermented C6 sugars, the hemicellulose fraction is principally a polymer of C5 sugars; with quite different characteristics for recovery and fermentation, the cellulose and hemicellulose in biomass are bound together in a complex framework of crystalline organic material known as lignin.

These differences mean that recovery of these biomass sugars is more complex than recovery of sugars from a starch feed. Once recovered, fermentation is also more complex than a simple fermentation of C6 sugars. The current focus focuses on the issues of releasing the sugars (hydrolysis) and then fermenting as much of the C6 and C5 sugars as possible to produce ethanol.

There are several different methods of hydrolysis: (i) concentrated sulfuric acid, (ii) dilute sulfuric acid, (iii) nitric acid, and (iv) acid pretreatment followed by enzymatic hydrolysis.

Ethanol is produced from the fermentation of sugar by enzymes produced from specific varieties of yeast. The five major sugars are the five-carbon xylose and arabinose and the six-carbon glucose, galactose, and mannose. Traditional fermentation processes rely on yeasts that convert six-carbon sugars to ethanol. Glucose, the preferred form of sugar for fermentation, is contained in both carbohydrates and cellulose. Because carbohydrates are easier than cellulose to convert to glucose, the majority of ethanol currently produced in the United States is made from corn, which produces large quantities of carbohydrates. Also, the organisms and enzymes for carbohydrate conversion and glucose fermentation on a commercial scale are readily available.

The conversion of cellulosic biomass to ethanol parallels the corn conversion process. The cellulose must first be converted to sugars by hydrolysis and then fermented to produce ethanol. Cellulosic feedstocks (composed of cellulose and hemicellulose) are more difficult to convert to sugar than are carbohydrates. Two common methods for converting cellulose to sugar are dilute acid hydrolysis and concentrated acid hydrolysis, both of which use sulfuric acid.

Dilute acid hydrolysis occurs in two stages to take advantage of the differences between hemicellulose and cellulose. The first stage is performed at low temperature to maximize the yield from the hemicellulose, and the second, higher temperature stage, is optimized for hydrolysis of the cellulose portion of the feedstock. Concentrated acid hydrolysis uses a dilute acid pretreatment to separate the hemicellulose and cellulose. The biomass is then dried before the addition of the concentrated sulfuric acid. Water is added to dilute the acid and then heated to release the sugars, producing a gel that can be separated from residual solids. Column chromatographic is used to separate the acid from the sugars.

Both the dilute and concentrated acid processes have several drawbacks. Dilute acid hydrolysis of cellulose tends to yield a large amount of by-products. Concentrated acid hydrolysis forms fewer by-products, but for economic reasons, the acid must be recycled. The separation and concentration of the sulfuric acid adds more complexity to the process. The concentrated and dilute sulfuric acid processes are performed at high temperatures (100 to 220°C, 212 to 430°F) which can degrade the sugars, reducing the carbon source and ultimately lowering the ethanol yield. Thus, the concentrated acid process has a smaller potential for cost reductions from process improvements such as acid recovery and sugar yield for the concentrated acid process could provide higher efficiency for both technologies.

Another approach involves countercurrent hydrolysis, a two-stage process. In the first stage, cellulose feedstock is introduced to a horizontal co-current reactor with a conveyor. Steam is added to raise the temperature to 180°C

(no acid is added at this point). After a residence time of approximately 8 minutes, during which some 60% of the hemicellulose is hydrolyzed, the feed exits the reactor. It then enters the second stage through a vertical reactor operated at 225°C (440°F). Very dilute sulfuric acid is added to the feed at this stage, where virtually all of the remaining hemicellulose and, depending on the residence time, anywhere from 60% to all of the cellulose is hydrolyzed. The countercurrent hydrolysis process offers higher efficiency (and, therefore, cost reductions) than the dilute sulfuric acid process. This process may allow an increase in glucose yields to 84%, an increase in fermentation temperature to 55°C (131°F), and an increase in fermentation yield of ethanol to 95%.

The greatest potential for ethanol production from biomass, however, lies in enzymatic hydrolysis of cellulose. The enzyme cellulase, now used in the textile industry to stone wash denim and in detergents, simply replaces the sulfuric acid in the hydrolysis step. The cellulase can be used at lower temperatures, 30 to 50°C, which reduces the degradation of the sugar. In addition, process improvements now allow simultaneous saccharification and fermentation (SSF). In the saccharification and fermentation process, cellulase and fermenting yeast are combined, so that as sugars are produced, the fermentative organisms convert them to ethanol in the same step. Once the hydrolysis of the cellulose is achieved, the resulting sugars must be fermented to produce ethanol. In addition to glucose, hydrolysis produces other six-carbon sugars from cellulose and five-carbon sugars from hemicellulose that are not readily fermented to ethanol by naturally occurring organisms. They can be converted to ethanol by genetically engineered yeasts that are currently available, but the ethanol yields are not sufficient to make the process economically attractive. It also remains to be seen whether the yeasts can be made hardy enough for production of ethanol on a commercial scale.

A large variety of feedstocks is currently available for producing ethanol from cellulosic biomass. The materials being considered can be categorized as agricultural waste, forest residue, and energy crops. Agricultural waste available for ethanol conversion includes crop residues such as wheat straw, corn stover (leaves, stalks, and cobs), rice straw, and bagasse (sugar cane waste). Forestry waste includes underutilized wood and logging residues; rough, rotten, and salvable dead wood; and excess saplings and small trees. Energy crops, developed and grown specifically for fuel, include fast-growing trees, shrubs, and grasses such as hybrid poplars, willows, and switchgrass.

Briefly, corn stover is the leaves and stalks of field crops, such as corn (maize), sorghum or soybean that are commonly left in a field after harvesting the grain. It is similar to straw, the residue left after any cereal grain or grass has been harvested at maturity for its seed. It can be directly grazed by cattle or dried for use as fodder; stover has attracted some attention as a potential fuel source, and as a biomass feedstock for fermentation or as a feedstock for ethanol production from cellulose.

Although the choice of feedstock for ethanol conversion is largely a cost issue, feedstock selection has also focused on environmental issues. Materials normally targeted for disposal include forest thinnings collected as part of an effort to improve forest health, and certain agricultural residues, such as rice straw. Also, forest residues represent an opportunity to decrease the fire hazard associated with the dead wood present in many forests. Small quantities of forest thinnings can be collected at relatively low cost, but collection costs rise rapidly as quantities increase.

Agricultural residues, in particular corn stover, represent a tremendous resource base for biomass ethanol production. Agricultural residues, in the long term, would be the sources of biomass that could support substantial growth of the ethanol industry. At conversion yields of around 60 to 100 gallons per dry ton, the available corn stover inventory would be sufficient to support 7 to 12 billion gallons of ethanol production per year.

Dedicated energy crops such as switchgrass, hybrid willow, and hybrid poplar are another long-term feedstock option. Switchgrass is grown on a 10-year crop rotation basis, and harvest can begin in year 1 in some locations and year 2 in others. Willows require a 22-year rotation, with the first harvest in year 4 and subsequent harvests every 3 years thereafter. Hybrid poplar requires 6 years to reach harvest age in the Pacific Northwest, 8 years in the Southeast, Southern Plains, and South Central regions, and 10 years in the Corn Belt, Lake States, Northeast, and Northern Plains regions.

The use of cellulosic biomass in the production of ethanol also has environmental benefits. Converting cellulose to ethanol increases the net energy balance of ethanol compared to converting corn to ethanol. The net energy balance is calculated by subtracting the energy required to produce a gallon of ethanol from the energy contained in a gallon of ethanol (approximately 76,000 Btu). Corn-based ethanol has a net energy balance of 20,000 to 25,000 Btu per gallon, whereas cellulosic ethanol has a net energy balance of more than 60,000 Btu per gallon. In addition, cellulosic ethanol use can reduce greenhouse gas emissions. Cellulosic ethanol can produce an 8 to 10% reduction in greenhouse gas emissions when used in E10 and a 68 to 91% reduction when used in E85.

Liquid Fuels – Methanol

Methanol is a colorless, odorless, and nearly tasteless alcohol and is also produced from crops and is also used as a fuel. Methanol, like ethanol, burns more completely but releases as much or more carbon dioxide than its gasoline counterpart. The balance is often seen as the various bi-processes that draw carbon dioxide from the atmosphere so there is no net modern release, as there is for fossil fuels.

Methanol and other chemicals were routinely extracted from wood in the 19th century and in the early 20th century. However, the original route for methanol recovery from biomass was quite different to current routes. Methanol was originally recovered from wood as a by-product of charcoal manufacture, and was often called *wood alcohol*. Pyrolysis (heating wood in the absence of air) to above 270°C (>520°F) in a retort causes thermal cracking or break-down of the wood and allows much of the wood to be recovered as charcoal. The watery condensate leaving the retort contained methanol, among other compounds. In 1923, commercial production of methanol from synthesis gas by a catalytic process was commenced. Now, almost all of the methanol used worldwide comes from the processing of natural gas.

In general, methanol production from natural gas feed consists of three steps: (i) generation of synthesis gas – in the case of natural gas feed, synthesis gas production consists of converting methane (CH_4) into carbon monoxide (CO) and hydrogen (H_2) via steam reforming, (ii) synthesis gas upgrading – primarily removal of carbon dioxide, plus any contaminants such as sulfur, and (iii) methanol synthesis and purification – reacting the carbon monoxide, hydrogen, and steam over a catalyst in the presence of a small amount of carbon dioxide and at elevated temperature and pressure. The methanol synthesis is an equilibrium reaction, and excess reactants must be recycled to optimize yields.

Modern methods proposed for the production of methanol from biomass involve the conversion of the biomass to a suitable synthesis gas, after which processing steps are similar to those developed for methanol from natural gas. However, the gasification techniques proposed are still at a relatively early stage of development using biomass feed and the methods are based on similar techniques used widely already with natural gas as feed.

Before biomass can be gasified, it must be pre-treated to meet the processing constraints of the gasifier. This typically involves size reduction, and drying to keep moisture contents below specific levels. Thereafter, biomass gasification involves heating biomass in the presence of low levels of oxygen (i.e., less than required for complete combustion to carbon dioxide and water). Above certain temperatures, the biomass will break down into a gas stream and a solid residue. The composition of the gas stream is influenced by the operating conditions for the gasifier, with some gasification processes more suited than others to producing a gas for methanol production. In particular, simple gasification with air creates a synthesis gas stream that is diluted with large quantities of nitrogen. This nitrogen is detrimental to subsequent processing to methanol, and so techniques using indirect gasification or an oxygen feed are preferred. For large-scale gasification, pressurized systems are considered to be more economic than atmospheric systems.

Once the economic optimum synthesis gas is available, the methanol synthesis takes place. This typically uses a copper-zinc catalyst at temperatures of 200 to 280°C and pressures of 50 to 100 atmospheres. The crude methanol from the synthesis loop contains water produced during synthesis as well as other minor by-products. Purification is achieved in multistage distillation, with the complexity of distillation dictated by the final methanol purity required.

Liquid Fuels – Propanol and Butanol

Propanol and butanol are considerably less toxic and less volatile than methanol. In particular, butanol has a high flashpoint (35°C; 95°F), which is a benefit for fire safety, but may be a difficulty for starting engines in cold weather.

The fermentation processes to produce propanol and butanol from cellulose are fairly tricky to execute, and the *Clostridium acetobutylicum* currently used to perform these conversions produces an extremely unpleasant smell, and this must be taken into consideration when designing and locating a fermentation plant. This organism also dies when the butanol content of whatever it is fermenting rises to 7%. For comparison, yeast dies when the ethanol content of its feedstock hits 14%. Specialized strains can tolerate even greater ethanol concentrations – so-called turbo yeast can withstand up to 16% ethanol. However, if ordinary *Saccharomyces* yeast can be modified to improve its ethanol resistance, scientists may yet one day produce a strain of the Weizmann organism with a butanol resistance higher than the natural boundary of 7%. This would be useful because butanol has a higher energy density than

ethanol, and because waste fiber left over from sugar crops used to make ethanol could be made into butanol, raising the alcohol yield of fuel crops without there being a need for more crops to be planted.

Liquid-Liquid Extraction

Liquid-liquid extraction is the commonest of the solvent extraction processes and is often the second choice, after distillation, when considering alternatives for separating large volumes of liquid mixtures. If the feedstock contains only a small amount of impurity and the impurity has a higher boiling point than the rest of the mixture, liquid-liquid extraction can even become preferable to distillation on an energy consumption basis. This is because distillation would have to vaporize almost all of the feed to recover the small amount of impurity.

Extraction could directly remove the minor component. Liquid extraction is widely used in the petroleum refining, chemical, and nuclear industries for the purification of aqueous and non-aqueous liquid process streams. However, the current use in waste minimization applications is largely confined to removal and recovery of organic materials from aqueous waste streams.

See also: Solvent Extraction, Supercritical Fluid Extraction.

Lithosphere

The lithosphere is outermost shell of the Earth that is composed of the crust and the portion of the upper mantle that behaves elastically on time scales of thousands of years or greater, defined on the mineralogy. The lithosphere is subdivided into tectonic plates which are the uppermost part of the lithosphere that chemically reacts to the atmosphere, the hydrosphere, and the biosphere through the soil-forming process (called the pedosphere). There are two types of lithosphere which are (i) the oceanic lithosphere, which is associated with the oceanic crust and exists in the oceanic basins and has a density of approximately of approximately 2.9 grams per cubic centimeter, and (ii) the continental lithosphere, which is associated with the continental crust and has a on the order of 2.7 grams per cubic centimeter.

The oceanic lithosphere consists mainly of a mafic mantle (mafic: an adjective describing a silicate mineral or igneous rock that is rich in magnesium and iron) crust and ultramafic mantle (over 90% mafic) and is denser than continental lithosphere. It thickens as it ages and moves away from the mid-ocean ridge. This thickening occurs by conductive cooling, which converts hot asthenosphere into lithospheric mantle. It was less dense than the asthenosphere for tens of millions of years, but after this becomes increasingly denser. The gravitational instability of mature oceanic lithosphere has the effect that when tectonic plates come together, oceanic lithosphere invariably sinks underneath the overriding lithosphere. New oceanic lithosphere is constantly being produced at mid-ocean ridges and is recycled back to the mantle at subduction zones, so oceanic lithosphere is much younger than its continental counterpart. The oldest oceanic lithosphere is approximately 170 million years old compared to parts of the continental lithosphere which are billions of years old.

On the other hand, the continental lithosphere (also called the continental crust) is the layer of igneous, sedimentary rock that forms the continents and the continental shelves. This layer consists mostly of granitic rock. Continental crust is also less dense than oceanic crust, although it is considerably thicker. Approximately 40% of the surface of the Earth is covered by continental crust, but continental crust makes up approximately 70% v/v of the crust of the Earth. The continental crust is believed to have been derived from the fractional differentiation of oceanic crust over geologic time (hundreds of millions of years) and was primarily a result of volcanism and subduction.

The lithosphere is underlain by the asthenosphere, which is the weaker, hotter, and deeper part of the upper mantle. The lithosphere-asthenosphere boundary is defined by a difference in response to stress in which the lithosphere remains rigid for long periods of geologic time in which it deforms elastically and through brittle failure. On the other hand, the asthenosphere undergoes considerable deformation and accommodates strain through this deformation.

Logging Residue

The various types of logging residue include stumps, tops, limbs, and unutilized cull trees. Stump residue, the part of the tree that is lower than the cutting point and thus left after the harvesting operation, is generally not available

commercially since the cost of obtaining the stump or root biomass is likely prohibitive. Tops refer to the tops of the trees that are either broken during harvesting or are cut off the central stem of the tree due to a merchantability standard. Limbs refer to the branches of the trees.

Cull trees are the trees that cannot be used to produce saw logs due to defects, rot, or form. Some cull trees are used as pulpwood, and others are left unutilized as a part of logging residue. Tops, limbs, and unutilized cull trees are the logging residue that is potentially available as biomass for energy production or chemical extraction.

Logs and Woodchips

Log-fired heating conjures up images of open fires and log stoves for many people, but there are also sophisticated, controllable, log-boilers available which can provide central heating and hot water. Logs are readily available in many areas where there are existing markets for domestic fuel wood. Logs should be well seasoned before burning to ensure the most efficient combustion, and should ideally be stored under cover in a well ventilated log store for a year or more.

Logs are ideal for providing heat for domestic buildings and are suitable for heating loads of up to around 50 kW. Log heating systems do require manual stoking once a day, which makes logs less convenient than more automated heating systems such as woodchips and pellets. Log-fired systems are available with outputs greater than 500 kW to heat larger building such as village halls; however, these larger systems will require more frequent fueling.

Wood chips are made from whole trees, branch wood, or coppice products which have been mechanically shredded by a chipping machine. For some types of boilers, the wood needs to have been air-dried before chipping, or the chips dried before burning. Wood chips are a bulky fuel and sufficient storage and delivery access needs to be considered when designing a heating system.

The use of a timber resource for local woodchip heating would provide a valuable economic return and stimulate the rural economy. Woodchip systems can provide automated, clean, and convenient heating for larger domestic properties with outputs of 20 to 30 kW, up to large-scale systems for hospitals, factories, schools, and district heating schemes with heating loads in the megawatt range. Woodchips can also be used to fuel combine heat and power plants in which the heat produced during electricity generation is used to provide hot water, and is not lost as in conventional power stations.

See also: Biomass, Wood.

Low-Btu Gas

Low-BTU gas consisting of a mixture of carbon monoxide, hydrogen, and some other gases with a heating value typically less than 300 Btu/scf (Btu/ft³, Btu ft⁻³).

For production of low Btu gases, air is typically used as a combusting (or, gasifying) agent. Since air, instead of pure oxygen, is used, the product gas inevitably contains a large concentration of undesirable constituents like nitrogen or nitrogen-containing compounds. Therefore, it unavoidably results in a low heating value of 150-300 Btu/scf. Sometimes, this type of gasification of coal may be carried out in-situ, i.e., underground, where mining of coal by other techniques is not economically favorable. For such in-situ gasification, low-Btu gas may be a desired product.

Low-Btu gas contains five principal components with around 50% v/v nitrogen, some quantities of hydrogen and carbon monoxide (combustible), carbon dioxide, and some traces of methane. The presence of such high contents of nitrogen makes the product gas be classified as "low Btu." The other two non-combustible components (CO₂ and H₂O) further lower the heating value of the product gas. The presence of these components limits the applicability of low-Btu gas to chemical synthesis. The two major combustible components are hydrogen and carbon monoxide, whose ratio varies depending on the gasification conditions employed. One of the most undesirable components is hydrogen sulfide (H₂S) whose content is proportional to the sulfur content of the original coal. It must be removed by gas cleaning procedures before product gas can be used for other useful purposes such as further processing and upgrading.

See also: Gasification, Gasification of Biomass.

Lower Explosive Limit

The lower explosive limit is the lower explosive limit of a gas or vapor at ordinary (ambient) temperature is the percent by volume of the gas vapor in air and is the lower limit at which the gas explodes or inflames. Conversely, the upper explosive limit of a gas or vapor at ordinary (ambient) temperature is the percent by volume of the gas vapor in air and is the upper limit at which the gas explodes or inflames (Table L-5).

Table L-5 Examples of the lower and upper explosive limits of selected chemicals in air.

Chemical	LEL	UEL
1,3-Butadiene	2.0	12.0
1-Butene	1.6	10.0
Benzene	1.3	7.9
Butane	1.8	8.4
Carbon Monoxide	12.5	74.0
Carbonyl Sulfide	12.0	29.0
Cyclohexane	1.3	7.8
Cyclopropane	2.4	10.4
Dimethyl Ether	3.4	27.0
Ethane	3.0	12.4
Ethanol	3.3	19.0
Ethylene	2.7	36.0
<i>Chemical</i>	<i>LEL</i>	<i>UEL</i>
<i>Chemical</i>	<i>LEL</i>	<i>UEL</i>
Heptane	1.1	6.7
Hexane	1.2	7.4
Hydrogen	4.0	75.0
Hydrogen sulfide	4.0	44.0
Isobutane	1.8	8.4
Isobutylene	1.8	9.6
Methane	5.0	15.0
Methanol	6.7	36.0
Methyl mercaptan	3.9	21.8
Propylene	2.4	11.0
Toluene	1.2	7.1
Xylene	1.1	6.6

Similarly, the lower flammability limit is the minimum concentration by volume of a combustible substance that is capable of propagating a flame under specified conditions and the upper flammability limit is the maximum concentration by volume of a combustible substance that is capable of continued propagation of a flame under the specified conditions.

However, these limits are to be used as a guide only since, under a variety of other circumstances, methane and the other hydrocarbon constituents of natural gas are explosive and flammable.

See also: Explosive Limits, Lower Flammability Limit, Upper Explosive Limit, Upper Flammability limit.

Lower Flammability Limit

Flammability limits, also called flammable limits, or *explosive limits* give the proportion of combustible gas in a mixture, between which limits this mixture is flammable. Gas mixtures consisting of combustible, oxidizing, and inert gases are only flammable under certain conditions.

The lower flammability limit is the minimum concentration by volume of a combustible substance that is capable of propagating a flame under specified conditions. The lower flammability limit (LFL), usually expressed in volume per cent, is the lower end of the concentration range of a flammable solvent at a given temperature and pressure for which air/vapor mixtures can ignite. The upper flammability limit (UFL) (upper explosive limit) gives the richest flammable mixture. An increase in the proportion of inert gas in a mixture raises the lower flammability limit.

The flammability range is delineated by the upper and lower flammability limit. Outside this range of air/vapor mixtures, the mixture will not ignite (unless heated). The lower flammability limit decreases with increasing temperature – a mixture that is below its lower flammability limit at a given temperature may ignite if heated sufficiently.

The lower flammability limit is typically close to the saturated vapor concentration at the flash point; however, due to differences in technique between measuring lower flammability limit and the various flash points (open/closed cup as well as different apparatus), some spread in the data usually exists.

See also: Lower Explosive Limit, Upper Explosive Limit, Upper Flammability Limit.

Lower Heating Value

The lower heating value (net calorific value, net CV, or LHV) of a fuel is defined as the amount of heat released by combusting a specified quantity (initially at 25°C or another reference state) and returning the temperature of the combustion products to 150°C.

The lower heating value assumes all the water component is in vapor state at the end of combustion (in product of combustion), as supposed to higher heating value which that assumes all the water component in liquid form of the combustion gas.

The lower heating value assumes that the latent heat of vaporization of water in the fuel and the reaction products is not recovered. It is useful in comparing fuels where condensation of the combustion products is impractical, or heat at a temperature below 150°C cannot be put to use.

See also: Low-Btu Gas, Low Heat Content Gas.

Low-Heat Content Gas

Low-heat content gas (low-BTU gas) is a mixture of coal gases containing nitrogen with a heat content of 100-200 Btu/ft³ produced in gasification processes using air as the oxygen source. It is the air-blown form of producer gas.

During the production of coal gas by oxidation with air, the oxygen is not separated from the air and, as a result, the gas product invariably has a low heat-content (150 to 300 Btu/ft³). Low heat-content gas is also the usual product of in situ gasification of coal which is used essentially as a method for obtaining energy from coal without the necessity of mining the coal, especially if the coal cannot be mined or of mining is uneconomical.

Several important chemical reactions, and a host of side reactions, are involved in the manufacture of low heat-content gas under the high temperature conditions employed. Low heat-content gas contains several components, four of which are always major components present at levels of at least several percent; a fifth component, methane, is marginally a major component.

The nitrogen content of low heat-content gas ranges from somewhat less than 33% v/v to slightly more than 50% v/v and cannot be removed by any reasonable means; the presence of nitrogen at these levels makes the product gas *low heat-content* by definition. The nitrogen also strongly limits the applicability of the gas to chemical synthesis. Two other noncombustible components (water, H_2O , and carbon dioxide, CO_2) further lower the heating value of the gas; water can be removed by condensation and carbon dioxide by relatively straightforward chemical means.

The two major combustible components are hydrogen and carbon monoxide; the H_2/CO_2 ratio varies from approximately 2:3 to approximately 3:2. Methane may also make an appreciable contribution to the heat content of the gas. Of the minor components, hydrogen sulfide is the most significant and the amount produced is, in fact, proportional to the sulfur content of the feed coal. Any hydrogen sulfide present must be removed by one, or more, of several procedures.

Low heat-content gas is of interest to industry as a fuel gas or even, on occasion, as a raw material from which ammonia, methanol, and other compounds may be synthesized.

See also: Low-Btu Gas, Lower Heating Value.

Low-Temperature Char

Char is produced by the low-temperature (approximately 650°C; 1,200°F) carbonization of coal. The two major properties of low-temperature char which make it a useful fuel are its clean, smokeless combustion and its relatively high reactivity. Current environmental regulations may make the smokeless quality of char even more desirable. Furthermore, carbonization leads to an appreciable loss of sulfur as well as undesirable trace elements, so that the char is a *cleaner* fuel than the original coal.

The fact that the low-temperature char is quite reactive means that ignition and burning will be efficient, a desirable property for fuel to be used in open-bed furnaces.

Another potential advantage of low-temperature char involves its production from very low-rank fuels, such as lignite or brown coal. These abundant fuels have low heat values and high water contents, but low-temperature carbonization can convert these fuels to a high-heat (per unit weight) char. Thus, there is the potential for conversion of these coals at the mine site by means of volatile gases (or chars) to generate electricity while the premium quality solid fuel (char) is transported elsewhere for use.

As active thermal decomposition proceeds and is followed by secondary degasification, the solid residues are progressively aromatized and homogenized by growth of graphitic lamellae which are increased in size by heating to higher temperatures. However, the properties of the chars which give an indication of lamellar growth and graphitic ordering (as the more familiar stacks of lamellae) do not change to any marked degree until temperatures on the order of 500 to 550°C (930 to 1020°F) are reached. In addition, the ultrafine pore structure of the coal may be retained until temperatures on the order of 650 to 700°C (1,200 to 1,290°F) are reached.

Lurgi Combined Reforming Process

The Lurgi combined reforming process was originally developed for large-scale methanol production, and it is with an example from this application that it is described here. In the context of the production of liquid fuels, it is suitable as a building block for the methanol-to-gasoline (MTG) process or the olefins-to-gasoline, and distillates (MOGD) process. For the high-pressure Synthol process, carbon dioxide needs to be purged from the system. The conventional tubular steam reforming process as used for methanol syngas production produces a hydrogen/carbon monoxide ratio of over 4 and a stoichiometric ratio of 2.6 to 2.9 (i.e., a hydrogen-rich gas) depending on the quality of the natural gas feedstock.

Auto-thermal reforming or partial oxidation produces carbon monoxide-rich gases with a hydrogen/carbon monoxide ratio in the range 1.5 to 3.5 and a stoichiometric number of approximately around 1.8.

Approximately half the feed is processed in the tubular primary reformer. The other half, together with the primary reformer effluent, is auto-thermally reformed with pure oxygen in the secondary reformer. Besides matching hydrogen-rich and carbon monoxide-rich process steps to produce an optimum stoichiometric ratio, the Combined Reforming process has beneficial effects such as:

The methane slip of the overall reforming process is governed by the temperature of the secondary reformer that is not subject to the same limitations of tube metallurgy as the tubular reformer. The combined process can thus provide a lower methane slip.

Less synthesis gas of the optimized quality is required per ton of methanol, reducing both the syngas compressor load and the capital cost of the synthesis unit.

The operating temperature of the primary reformer need no longer be chosen to minimize methane slip. The reformer can be operated under mild conditions. The higher operating pressure thus possibly enables the syngas compressor load to be further reduced.

The reduced throughput through the primary reformer together with the lower operating temperature combine to reduce the tubular reformer to approximately 25% of the size of that required for the single-stage process. This reduces the stack gas losses referred to earlier by the same amount.

One feature common to all Fischer-Tropsch processes is the inherent lack of selectivity. The actual selectivity will depend on the desired product slate as well as on the catalyst and the operating conditions. In all cases, however, substantial quantities of gaseous hydrocarbon derivatives including methane are produced.

In principle, it is desirable to recycle these gaseous hydrocarbon derivatives to produce more synthesis gas. On the other hand, it is necessary to provide a purge of inert gases, principally argon and nitrogen. The other aspect of selectivity that requires recognition is that a proportion of higher-molecular-weight products, including waxes, is produced and may require hydrotreating for conversion to a saleable product.

The Syntroleum process is a gas-to-liquids technology that has been in use for several decades. A major advantage is that the process uses compressed air instead of pure oxygen to facilitate the conversion reaction, substantially reducing the capital costs and vastly improving the safety of the process plants.

Lurgi Dry Ash Gasifier

The Lurgi dry ash gasifier is a relatively high-pressure, moderate-temperature moving bed gasifier that is typically used for the production of gas from coal but lends itself to the production of gas from biomass.

There are several reaction zones in the gasifier. Devolatilization, including the vaporization of coal moisture, occurs at the top where the incoming coal is heated by the rising hot gases. Further down where the coal char reaches temperatures of 650 to 815°C (1,200 to 1,500°F), the gasification reactions proceed. Temperatures in the bottom combustion zone, where the coal burns to supply heat for the endothermic gasification reactions, are kept below the ash melting point, which may vary from approximately 980 to 1,370°C (1,800 to 2,500°F) depending on the feedstock. Biomass feedstocks would not require such severe temperatures.

As for moving bed gasifiers, the Lurgi gasifier does not readily handle fines, and caking or swelling coals generally require an oxidative pretreatment or internal agitation to prevent plugging and resultant excessive pressure drops. The coal is crushed and screened to between 3 and 40 mm, and the fines are removed and used for raising steam in pulverized coal boilers. If the coal is very friable, the fines content may exceed plant fuel requirements and must be disposed of or sold. Predrying the coal is not necessary; lignite with moisture contents up to 35% may be used directly. Ash contents up to 35% or more are also not a problem, although the poorer heat transfer characteristics of ash may require increased steam rates to prevent clinkering. The sized coal is introduced through the coal lock hopper into the reactor.

Coal residence time within the gasifier is approximately one hour. The ash is withdrawn through the ash lock hopper at the bottom. Heat recovery in this counterflow system is good; the ash is cooled to approximately 400 to 500°C (750 to 930°F) by the incoming steam/oxygen mixture, while the off gases are cooled to 200 to 540°C depending on the moisture in the coal.

Much of the steam introduced into the gasifier is used to control the temperature in the combustion zone, with up to 50% of the steam passing through the system unreacted. High steam concentrations do, however, serve to shift the equilibrium of the carbon-steam and the gas shift reactions to promote hydrogen formation. The intermediate gasification zone temperature results in some methane formation, although much of the methane in the off gas probably results from coal pyrolysis in the devolatilization zone. Tars and oils are also released in this zone and exit with the off gases from which they are later removed by washing with water in the scrubber/cooler.

See also: Gasification, Gasification of Biomass.

Lurgi Process

Lurgi GMBH is currently involved in the design and supply of synthesis gas production units for two major synfuel projects – one based on the Sasol Synthol process and the other using the Shell SMDS synthesis. There is a substantial difference in the hydrogen/carbon monoxide ratios required by the two processes, and this has led to the selection of different syngas production routes.

As an example of a fixed-bed process, the Lurgi process was developed in Germany before World War II and is a process that is adequately suited for large-scale commercial production of synthetic natural gas. The older Lurgi process is a dry ash gasification process which differs significantly from the more recently developed slagging process. The dry ash Lurgi gasifier is a pressurized vertical kiln which accepts crushed ($1/4 \times 1.75$ inches., 6×44 mm) noncaking coal and reacts the moving bed of coal with steam and either air or oxygen.

The feedstock is gasified at 350 to 450 psi, and devolatilization takes place in the temperature range 615 to 760°C (1,140 to 1,400°F), and the residence time in the reactor is approximately 1 hour. Hydrogen is supplied by injected steam, and the necessary heat is supplied by the combustion of a portion of the product char. The revolving grate, located at the bottom of the gasifier, supports the bed of coal, removes the ash, and allows steam and oxygen (or air) to be introduced.

The product gas has high methane content relative to the products from non-pressurized gasifier units. With oxygen injection, the gas has a heat content of approximately 450 Btu/ft³. The crude gas which leaves the gasifier contains tar, oil, phenols, ammonia, coal fines, and ash particles. The steam is first quenched to remove the tar and oil, and, prior to methanation, part of the gas passes through a shift converter and is then washed to remove naphtha and unsaturated hydrocarbon derivatives; a subsequent step removes the acid gases. The gas is then methanated to produce a high heat-content pipeline quality product.

The Wellman Galusha process – also a fixed-bed process – has been in commercial use since the early decades of the 20th century. The two types of gasifiers, the standard type and the agitated type and the rated capacity of an agitated unit may be 25% or more higher than that of a standard gasifier of the same size. In addition, an agitated gasifier is capable of treating volatile caking bituminous coals.

The gasifier is water-jacketed, and, therefore, the inner wall of the vessel does not require a refractory lining. Agitated units include a varying speed revolving horizontal arm which also spirals vertically below the surface of the coal bed to minimize channeling and to provide a uniform bed for gasification. A rotating grate is located at the bottom of the gasifier to remove the ash from the bed uniformly. Steam and oxygen are injected at the bottom of the bed through tuyeres. Crushed coal is fed to the gasifier through a lock hopper and vertical feed pipes. The fuel valves are operated so as to maintain a relatively constant flow of coal to the gasifier to assist in maintaining the stability of the bed and, therefore, the quality of the product gas.

Lurgi Slagging Gasifier

The Lurgi slagging gasifier (slagging Lurgi gasifier) is an improved version of the Lurgi dry ash gasifier. In the gasifier, the temperature of the combustion zone is kept higher than the ash fusion point by using a smaller amount of steam. The ash is removed from the bottom as slag.

The slagging gasifier is based on the original Lurgi dry ash gasifier, but was intended to improve upon it in the following respects: (i) produce non-leachable vitreous slag rather than dry ash, (ii) improve specific reactor throughput, (iii) increase fines content acceptable in feed, (iv) reduce steam consumption and consequent gas condensate production, (v) recycle tars to extinction, and (vi) increase carbon monoxide and hydrogen (CO/H_2) yields.

In the process, the feedstock is introduced at the top of the water-cooled and refractory-lined gasifier via a lock hopper system. The gasifier is provided with a motor-driven coal distributor/mixer to stir and evenly distribute the incoming coal mixture, which then gradually descends through several process zones. The feedstock at the top of the bed is dried and devolatilized. The descending feedstock is transformed into char, and then passes into the gasification (reaction) zone. Below this zone, oxygen and steam are introduced into the gasifier vessel through side-wall-mounted tuyeres (lances) at the combustion zone, where any remaining char is burned out and slag formation occurs. Slag is withdrawn from the slag pool by means of an opening in the hearth plate at the bottom of the gasifier vessel. The slag flows downward into a quench chamber and lock hopper in series. The pressure differential between the quench chamber and gasifier regulates the flow of slag between the two vessels.

The product gas exits the gasifier at approximately 450°C (840°F) through an opening near the top of the gasifier vessel and passes into a water quench vessel and a boiler feed water preheater designed to lower the temperature to approximately 150°C (300°F). Entrained solids and soluble compounds mixed with the exiting liquid are sent to a gas-liquor separation unit. Soluble hydrocarbons such as tars, oils, and naphtha are recovered from the aqueous liquor and recycled to the top of the gasifier and/or reinjected at the tuyeres.

The main advantage of this gasifier over the conventional dry ash gasifier is that the yield of carbon monoxide and hydrogen is high and the coal throughput increases many times; also, steam consumption is minimized.

Lye Treating Process

Typically, the term lye is a metal hydroxide that is obtained by leaching wood ashes, or it is a strong alkali which is soluble producing. Lye most commonly refers to sodium hydroxide (NaOH), but has also been used to refer to potassium hydroxide (KOH).

Thus, lye treating is a process for removing acidic constituents from liquid fuels and other products. The process is carried out in continuous treaters, which essentially consist of a pipe containing baffles or other mixing devices into which the oil and lye solution are both pumped. The pipe discharges into a horizontal tank where the lye solution and oil separate. Treated oil is withdrawn from near the top of the tank; lye solution is withdrawn from the bottom and recirculated to mix with incoming untreated oil. A lye-treating unit may be incorporated as part of a processing unit; for example, the overhead from a bubble tower may be condensed, cooled, and passed immediately through a lye-treating unit. Such a unit is often referred to as a worm-end treater since the unit is attached to the particular unit as a point beyond the cooling coil or cooling worm.

Caustic solutions ranging from 5 to 20% w/w are used at 20 to 45°C (70 to 110°F) and 5 to 40 psi. High temperatures and strong caustic are usually avoided because of the risk of color body formation and stability loss. Caustic-product treatment ratios vary from 1:1 to 1:10.

M85

M85 is an alcohol fuel mixture containing 85% v/v methanol and 15% v/v gasoline by volume. Methanol is typically made from natural gas, but can also be derived from the fermentation of biomass (such as wood, hence wood alcohol). Because it is easier to transport natural gas to a distant market by converting it to methanol, which is a liquid at ordinary temperatures and pressures, than by chilling and liquefying it or by building a long pipeline, some crude oil-exporting countries are looking at exporting their waste natural gas (which they currently dispose of by flaring) by converting it to methanol.

There have been efforts to introduce M85 into various fuel markets, notably in California, but there is no nationwide transportation network in place for this as a bulk fuel (on the scale of gasoline, diesel fuel, or natural gas) yet. There are still not very many M85 stations in the United States. However, only relatively small changes need to be made to a gasoline fueling station (such as linings and seals in tanks, pumps, and dispensers) in order to handle M85, compared to the completely new construction needed to handle compressed natural gas (CNG), liquefied natural gas (LNG), or liquefied crude oil gas (LPG), so M85 capability can be added in quickly if local governments, consumers (usually fleets), and retailers decide to develop a market.

Alcohol fuels, such as M85, are perhaps the least distinguishable from gasoline in how they are purchased and used, which should ease acceptance. The fuel system of a car or truck only needs to be slightly changed (somewhat different materials, bigger fuel injectors, and a fuel composition sensor) in order for it to run on M85, and recently, automakers have been offering M85 vehicles at no extra cost over their gasoline counterparts (or even for slightly less money), though at present, automakers seem to be more interested in ethanol-gasoline blends (such as E85).

Most M85 vehicles are flex-fuel vehicles, which means that any mixture of M85 and gasoline in the fuel tank can be used by the engine – a fuel-composition sensor tells the engine computer what percentage of methanol is in the fuel, and it adjusts the injectors and ignition accordingly. Thus, an M85 vehicle is a gasoline vehicle if M85 is not available.

Methanol is more corrosive than gasoline (though it is less toxic and not carcinogenic); this is why an automaker needs to change some of the materials in the fuel-handling systems of both the vehicle and the refueling station to materials that can withstand attack by the fuel. Special oil additives are necessary in order to protect the engine. Also, because the mixture of air to fuel is much richer than gasoline (approximately 8 to 1 by weight, compared to approximately 14 to 1 for gasoline), there is more liquid fuel available to wash oil off of cylinder walls during a cold start.

The richer fuel/air mixture needed by methanol also means that a given volume of gasoline will take you approximately 70% farther than the same tank full of M85; most automakers have at least partially compensated for this by putting a larger fuel tank in their M85 vehicles.

The reason that methanol is most commonly used in a mixture with 15% v/v gasoline is to correct for two disadvantages of pure methanol: (i) a methanol flame is colorless, so gasoline is added to give the flame some color so rescuers can tell if a fire is present should an M85 vehicle get into a crash, and (ii) methanol, being a pure chemical compound, has a single boiling point, so that it can cause cold-start problems in cold weather, or vapor lock in hot.

Gasoline, being a mixture of compounds with different boiling points, always has some components that will remain in the liquid phase and vaporize at a given temperature, so adding it to methanol confers this flexibility on the M85 mixture. As a result, some manufacturers recommend mixing additional gasoline with M85 in the extremely cold weather of northern winters.

Macroalgae

Macroalgae, or seaweeds as they are sometimes called, are also loosely defined as algae that are visible to the naked eye.

Among renewable energy sources, biomass represents the most ready to be implemented on a large scale without any environmental or economic penalty. The photosynthetic efficiency of aquatic biomass results to be much higher (generally 6 to 8%, average) than that of terrestrial (approximately 2%). This makes the former more adaptable for an enhanced carbon dioxide fixation to afford a high biomass production. Aquatic biomass presents an easy adaptability to grow in different conditions, both in fresh-water or marine-water, and in a wide enough range of pH.

Macroalgae are not microalgae or phytoplankton, though the spore stages of several species have been misidentified as species of phytoplankton in the past. Some macroalgae consist of many cells, while some microalgae consist of a single cell, but this is not always the case. Several macroalgae are single-celled, including *Acetabularia* and *Caulerpa*.

Seaweeds are primitive forms of plants, but because they lack vascular tissue, they are definitely algae. Macroalgae species are split into three groups based on their photosynthetic pigments: Phaeophyta (the browns), Rhodophyta (the reds) and Chlorophyta (the greens). Macroalgae, like seaweed, is not as widely used in the production of biodiesel. Microalgae have much more oil than macroalgae, and it is much faster and easier to grow.

Macroalgae are extensively grown and used as food in Asiatic countries, or as source of chemicals. They are usually collected from natural water basins where they are seasonally available. Only recently they have been considered for energy production.

The pond culture of algae presents the advantage of assimilating carbon dioxide emitted by electric power plants, using wastewater that may supply the amount of required nutrients. Either marine microalgae or seaweed could be used for solar energy conversion and biofuel production. Microalgae have received so far more attention with respect to macroalgae as agents for enhanced carbon dioxide fixation due to their facile adaptability to grow in ponds or bioreactors and the extended knowledge on several strains used for fish feeding.

In fact, macroalgae have enormous potential to be the best source of biomass for biofuel. Growing macroalgae in land-based ponds and boosting the growth with carbon dioxide, can be a major source of the algae biomass for biofuels applications. Using carbon dioxide to boost the growing can increase the yield. Macroalgae are the optimal source for second-generation bioethanol, due to (i) high in carbohydrates/polysaccharides and thin cellulose walls, (ii) high yield per growing area, (iii) grown on non-agriculture land, (iv) do not use fresh water, and (v) consumes large amounts of carbon dioxide while growing.

See also: Biomass, Microalgae.

Maize

Maize, also known as corn, is a cereal grain that was first domesticated by the indigenous people in southern Mexico approximately 10,000 years ago.

The crop is a feedstock for the production of biofuel due to the starch content and the comparatively easy conversion of the starch to ethanol. Unlike sugarcane, in which squeezed sugar water can be directly fermented, the corn starch must be converted using alpha and gluco-amylase enzymes to convert the starch to simple sugars. Cellulosic feedstocks are even more recalcitrant and require time and energy to convert to simple sugars.

The life cycle analysis (LCA) of ethanol production from corn grain has yielded a net energy ratio that represents a 20 to 45% positive energy balance in producing ethanol from corn. Environmental issues in corn production revolve around erosion, pesticide use, and nutrient use. Pesticides and nutrients have the potential to contaminate surface and ground water. Soil erosion has led to loss of topsoil and polluted streams and river systems with silt.

Manufactured Gas

Manufactured gas is a fuel-gas mixture made from other solid, liquid, or gaseous materials, such as crude oil, coal, coke, or biomass and should not be confused with natural gas. The principal types of manufactured gas are retort coal gas, coke oven gas, water gas, carbureted water gas, producer gas, oil gas, reformed natural gas, and reformed propane or liquefied petroleum gas (LPG). Several processes for making substitute natural gas (SNG) from coal have been developed. Most of the manufactured gas, as it fits into the context of this book, is produced by any one of three processes which, at the present time, find limited use but are still active processes on some areas, and these are: (i) coal carbonization process, (ii) the carbureted water gas process, and (iii) oil gas process.

The *coal carbonization process* was the primary commercial mode of manufacturing gas from ca 1816 to 1875. After 1875, newer processes and technologies gradually replaced coal carbonization. Coal gas was produced through the distillation of bituminous coal in heated, anaerobic vessels called retorts. In this process, coal was broken down into its volatile components through the action of heat in an anaerobic environment. During the retorting phase, approximately 40% w/w of the coal is converted into volatile gases and liquids while the remainder of the coal is converted into solids, primarily coke.

From the retort, some of the gaseous products are condensed (to liquids) and others remain in the gaseous state. The liquids (also called *liquors*) consist of water and coal tar. The products remaining in the gaseous phase are cooled to produce additional coal tar after which the gas is cooled further to remove any other non-gaseous impurities, such as ammonia and sulfur compounds. These are removed by washing the gas in water and by running the gas through beds of moist lime or moist iron oxides. After this final purification process, the coal gas is sent to storage.

The *carbureted water gas process* consists of enriching a form of coal gas, known as water gas (blue gas), to increase the heat content. Thus, by injecting oil into a vessel containing heated water gas, the oil and vapor combined form a gaseous fuel with a thermal content of approximately 300-350 Btu/ft³. Typically, a carbureted water gas plant consists of a brick-lined, cylindrical, steel vessel, the generator, the carburetor (carbureted), and a super-heater. As the gas exits the generator, it is passed into the carburetor where the oil is introduced into the vapor.

The *oil gas process* is similar to carbureted water gas process but consists of steam-cracking the oil in a steam environment to produce the raw gas rather than by distilling coal. From the generator, the gas is passed to a vaporizer, where it is enriched with additional injections of oil and then routed through a super heater. After exiting the super heater, the gas is scrubbed and processed for distribution in much the same way as was carbureted water gas. Many of the same waste products associated with the production of coal gas, notably tars containing polynuclear aromatic hydrocarbons (PNAs, or polyaromatic hydrocarbons, PAHs) were also generated during gas manufacture.

Material Balance

On any process, it is necessary to understand the concept of material balance. Material balance (mass balance) is an application of conservation of mass an expression for conservation of mass governed by the observation that the amount of mass leaving a control volume is equal to the amount of mass entering the volume minus the amount of mass accumulated in the volume.

$$M_{\text{original}} = M_{\text{remaining}} + M_{\text{removed}}$$

Furthermore, the pressures measured over time can be used to estimate the volume of hydrocarbon derivatives in place.

By accounting for material entering and leaving a system, mass flows can be identified which might have been unknown, or difficult to measure without this technique. The exact conservation law used in the analysis of the system depends on the context of the problem, but all revolve around mass conservation insofar as matter cannot be created spontaneously or be destroyed.

MDEA

Methyl diethanolamine is a clear, colorless, or pale yellow liquid with an ammonia-like odor. It is miscible with water, alcohol, and benzene. Methyl diethanolamine is also known as N-Methyl diethanolamine and more commonly as MDEA. It has the formula $\text{CH}_3\text{N}(\text{C}_2\text{H}_4\text{OH})_2$ and is a tertiary amine:

The alkanolamine derivatives and their respective aqueous solutions will absorb carbon dioxide and hydrogen sulfide at lower temperatures and release the acid gases at higher temperatures. This forms the basis for processes which separate carbon dioxide and hydrogen sulfide from gas streams.

Methyldiethanolamine is an alkanolamine used in gas treating and hydrogen sulfide enrichment units for selectively removing hydrogen sulfide from gas streams containing carbon dioxide. These units will, in most cases, permit 60 to 80% of the carbon dioxide to remain in the treated gas stream. Methyldiethanolamine is also used in natural gas plants for the bulk removal of carbon dioxide while producing a gas stream containing 0.25 grains hydrogen sulfide/100 ft³. Bulk carbon dioxide removal can be realized with methyldiethanolamine when the carbon dioxide/hydrogen sulfide ratio ranges from 100 to 1,000.

Similar compounds are monoethanolamine (MEA, $\text{HOCH}_2\text{CH}_2\text{NH}_2$), a primary amine, and diethanolamine (DEA, $\text{HOCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{OH}$), a secondary amine, both of which are also used for in amine (olamine) gas treating units.

See also: Gas Cleaning, MEA.

MEA

Mono-ethanolamine (2-aminoethanol, ethanolamine, and abbreviated as ETA or MEA) is an organic compound that is both a primary amine (due to an amino group in the molecule) and a primary alcohol (due to the hydroxyl group in the molecule):

Ethanamine (mono-ethanolamine)

Like other amines, monoethanolamine is a weak base as well as being a toxic, flammable, corrosive, colorless, viscous liquid with an odor similar to that of ammonia.

The alkanolamines and their aqueous solutions will absorb carbon dioxide and hydrogen sulfide at lower temperatures and release the acid gases at higher temperatures. This forms the basis for processes which separate carbon dioxide and hydrogen sulfide from gas streams.

Methyldiethanolamine is an alkanolamine used in gas treating and hydrogen sulfide enrichment units for selectively removing hydrogen sulfide from gas streams containing carbon dioxide. These units will, in most cases, permit 60 to 80% of the carbon dioxide to remain in the treated gas stream. Methyldiethanolamine is also used in natural gas plants for the bulk removal of carbon dioxide while producing a gas stream containing 0.25 grains hydrogen sulfide/100 scf. Bulk carbon dioxide removal can be realized with methyldiethanolamine when the carbon dioxide/hydrogen sulfide ratio ranges from 100 to 1,000.

Similar compounds are monoethanolamine (MEA, $\text{HOCH}_2\text{CH}_2\text{NH}_2$), a primary amine, and diethanolamine (DEA, $\text{HOCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{OH}$), a secondary amine, both of which are also used for in amine (olamine) gas treating units.

Mechanical Energy

Mechanical energy is the energy that is possessed by an object due to its motion or due to its position. Mechanical energy can be either (i) kinetic energy, which is energy of motion or (ii) potential energy, which is stored energy of position.

In the physical sciences, mechanical energy is the sum of the kinetic energy and the potential energy and is the energy associated with the motion and position of an object usually in some force field (such as a gravitational field). Mechanical energy (and also the thermal energy) can be separated into two categories which are (i) transient energy and (ii) stored energy. Transient energy is energy in motion, that is, energy being transferred from one place to another, while stored energy is the energy contained within a substance or object. Transient mechanical energy is commonly referred to as work, while stored mechanical energy exists in one of two forms which are (i) kinetic energy or (ii) potential energy.

More specifically, potential energy is the energy stored in an object subjected to a conservative force. Common types include the gravitational potential energy of an object that depends on its mass and its distance from the center of mass of another object. On the other hand, kinetic energy is the energy stored in an object because of its motion which depends on the speed of an object and is the ability of a moving object to do work on other objects when it collides with them.

The principle of conservation of mechanical energy states that if an isolated system is subject only to conservative forces, the mechanical energy is constant. However, if an object moves in the opposite direction of a conservative net force, the potential energy will increase, and if the speed of the object changes, the kinetic energy of the object also changes. In all real systems, however, non-conservative forces, such as frictional, will be present, but if they are of negligible magnitude, the mechanical energy changes little and its conservation is a useful approximation. In elastic collisions, the kinetic energy is conserved, but in when the collisions are non-elastic, some of the mechanical energy may be converted into thermal energy.

A modern wind turbine is an energy-converting machine to convert the kinetic energy of wind into mechanical energy and in turn into electrical energy. In the recent decades in the latter part of the 20th century, it has been estimated that advances in aerodynamics, structural dynamics, and micrometeorology may contribute to a 5% annual increase in the energy yield of wind turbines. Various wind turbine concepts have been developed and built for maximizing the wind energy output, minimizing the turbine cost, and increasing the turbine efficiency and reliability.

Medium-Btu Gas

Medium-BTU gas consists of a mixture of methane, carbon monoxide, hydrogen and various other gases with a heating value in the range of 300-700 Btu/scf.

In the production of medium-Btu gas, pure oxygen rather than air is used as combusting agent, which results in an appreciable increase in the heating value by approximately 300 to 400 Btu/ft³. The product gas predominantly contains carbon monoxide and hydrogen with some methane and carbon dioxide. It is primarily used in the synthesis of methanol, higher-molecular-weight hydrocarbon derivatives via Fischer-Tropsch synthesis, and a variety of other chemicals. It can also be used directly as a fuel to generate steam or to drive a gas turbine. The H₂/CO ratio in medium-Btu gas varies from 2:3 (CO-rich) to more than 3:1 (H₂-rich). The increased heating value is attributed to higher contents of methane and hydrogen as well as to lower concentration of carbon dioxide, besides the absence of nitrogen in the gasifying agent.

See also: Gasification, Gasification of Biomass, Medium Heat Content Gas.

Medium Heat Content Gas

Medium heat-content gas (*medium BTU gas*) has a heating value in the range 300 to 550 Btu/ft³ and the composition is much like that of low heat-content gas, except that there is virtually no nitrogen. The primary combustible gases in medium heat-content gas are hydrogen and carbon monoxide. Medium heat-content gas is considerably more

versatile than low heat-content gas; like low heat-content gas, medium heat-content gas may be used directly as a fuel to raise steam, or used through a combined power cycle to drive a gas turbine, with the hot exhaust gases employed to raise steam, but medium heat-content gas is especially amenable to synthesize methane (by methanation), higher hydrocarbon derivatives (by Fischer-Tropsch synthesis), methanol, and a variety of synthetic chemicals.

The reactions used to produce medium heat-content gas are the same as those employed for low heat-content gas synthesis, the major difference being the application of a nitrogen barrier (such as the use of pure oxygen) to keep diluent nitrogen out of the system.

In medium heat-content gas, the H_2/CO ratio varies from 2:3 C to 3:1 and the increased heating value correlates with higher methane and hydrogen contents as well as with lower carbon dioxide contents. Furthermore, the very nature of the gasification process used to produce the medium heat-content gas has a marked effect upon the ease of subsequent processing. For example, the CO_2 -acceptor product is quite amenable to use for methane production because it has (i) the desired hydrogen to carbon monoxide (H_2/CO) ratio just exceeding 3:1, (ii) an initially high methane content, and (iii) relatively low water and carbon dioxide contents. Other gases may require appreciable shift reaction and removal of large quantities of water and carbon dioxide prior to methanation.

Membrane

Membranes are fabricated in relatively small modules; for larger capacity, more modules are added. Cost is therefore virtually linear with capacity, making them more competitive at lower capacities. The design of membrane systems involves a tradeoff between pressure drop (or diffusion rate) and surface area, as well as between product purity and recovery. As the surface area is increased, the recovery of fast components increases; however more of the slow components are recovered, which lowers the purity.

The main gas separation methods are liquefaction/distillation, absorption, adsorption, and membrane-based processes. Membrane separation technologies are rapidly emerging as the preferred separation technology, particularly portable skid-mounted and packaged field processing units. Though, current membrane processes may be costly in some applications, they may be the only method for practical use in natural gas cleanup.

Until recently, the use of *membranes* for gas separation has been limited to carbon dioxide removal. Improvements in membrane technology have now made membranes competitive in other applications in the natural gas area. New membrane materials and configurations exhibit superior performance and offer improved stability against contaminants found in natural gas. The new membranes are targeted at three separations: nitrogen, carbon dioxide/hydrogen sulfide, and natural gas liquids. The process uses a two-step membrane system design; the methane-selective membranes do not need to be operated at low temperatures, and capital and operating costs are within economically acceptable limits.

New membranes have been developed for the gas industry. For example, the membranes allow permeation of condensable vapors, such as C_{3+} hydrocarbon derivatives, aromatics, and water vapor, while rejecting the non-condensable gases, such as methane, ethane, nitrogen, and hydrogen. During the past 15 years, more than 50 systems have been installed in the chemical process industry worldwide. The main applications are nitrogen removal, recovery of natural gas liquids, and dew-point control for associated natural gas and fuel gas conditioning for gas turbines and engines.

In another process, a membrane-based process for upgrading natural gas that contains C_{3+} hydrocarbon derivatives and/or acid gas is described. The conditioned natural gas can be used as fuel for gas-powered equipment, including compressors, in the gas field or the processing plant. Optionally, the process can be used to produce natural gas liquids.

Membrane Permeation

Membrane permeation is the selective diffusion of molecules through a solid polymer film and is also called pervaporation or perstraction when applied to liquid feeds. In fact, the membrane permeation process is a simple

application of selective diffusion through a permeable solid barrier. In its simplest form, the permeable solid barrier separates two chambers, one of which contains the feed stream at higher pressure and the other the product stream, which has diffused through the barrier to a lower pressure.

The concept can be applied to either liquid or gaseous feed mixtures but has found most of its commercial application to date in gas separation processes. In a similar manner to reverse osmosis, the feedstock stream is applied to one side of a solid polymer membrane and the flow of individual components of a feed through the solid polymer film is based on the concentration difference between the upstream and downstream sides of the film for each dissolved component.

For gas streams feedstocks, the concentrations of the components of the gas stream dissolved in the two sides of the membrane are a function of the partial pressure of each of the components in the feedstock and in the product stream. For liquid feedstocks, the downstream concentration is maintained at a low value by either (i) applying a vacuum or a sweep gas to the downstream side of the membrane or (ii) sweeping the downstream surface with a miscible, but easy to separate, solvent. The first configuration, pervaporation, is more common than the second configuration (perstraction). For liquid permeation, the concentrations of the feedstock components in the upstream surface of the membrane are a function of their concentrations in the feed liquid and their solubility in the membrane polymer.

Membrane Processes

Membrane processes commonly used for alternative energy systems are reverse osmosis, ultrafiltration, and microfiltration. Permeation and electrodialysis are also finding increasing use. With the exception of permeation, which is still considered a developing technology, all the above are commercial processes. These processes make use of a thin membrane barrier which can be produced with properties that vary over a wide spectrum. The membrane is essentially solid for reverse osmosis, permeation, and electrodialysis; it is porous with continuous discrete holes for microfiltration. Ultrafiltration membranes can be of either type depending on the application.

Generally, the processes are defined by the apparent pore size of the membrane barrier that is employed. This apparent pore size is reported for measured experimental diffusion rates even when it is known that no continuous pores or holes through the membrane exist because the form of the diffusion equations is the same for solid membranes and for porous membranes. The pore size reported for the solid barrier is that which will give the same flow rate for a given pressure drop through a membrane which does have continuous pores.

As they apply to alternative energy systems, membranes were (and still are) used for gas separation has been limited to carbon dioxide removal. Improvements in membrane technology have now made membranes competitive in other applications in the natural gas area. New membrane materials and configurations exhibit superior performance and offer improved stability against contaminants found in natural gas. The new membranes are used in processes for (i) nitrogen removal, (ii) carbon dioxide removal, (iii) hydrogen sulfide removal, and (iv) the removal of higher-molecular-weight hydrocarbon derivatives, also referred to as gas liquids and which includes the C2 to C5 hydrocarbons. The process uses a two-step membrane system design; the methane-selective membranes do not need to be operated at low temperatures, and capital and operating costs are within economically acceptable limits.

Gas permeation membranes are usually made with vitreous polymers that exhibit good diffusional selectivity. However, for separation to be effective, the membrane must be very permeable with respect to the contamination to be separated, which passes through the membrane driven by pressure difference, and it must be relatively impermeable to methane.

Membrane separation processes are designed to process a wide range of feedstocks and offer a simple solution for removal and recovery of higher-boiling hydrocarbon derivatives (natural gas liquids) from natural gas. The separation process is based on high-flux membranes that selectively permeates higher-boiling hydrocarbon derivatives (compared to methane) and are recovered as a liquid after recompression and condensation. The residue stream from the membrane is partially depleted of higher-boiling hydrocarbon derivatives, and is then sent to sales gas stream. Gas permeation membranes are usually made with vitreous polymers that exhibit good selectivity, but, to be effective, the membrane must be very permeable with respect to the separation process.

Membrane systems are very versatile and are designed to process a wide range of feed conditions. Gases can be separated by taking advantage of the difference in rates of diffusion through membranes. Gases that diffuse faster (including hydrogen) become the permeate stream and are available at low pressure, whereas the slower-diffusing gases become the non-permeate and leave the unit at a pressure close to the pressure of the feedstock at entry point. Membrane systems contain no moving parts or switch valves and have potentially high reliability. The major threat is from components in the gas (such as aromatics) that attack the membranes, or from liquids, which plug them.

With very compact footprint and low weight, these systems are well suited for offshore applications. New membranes allow permeation of condensable vapors, such as C_{3+} hydrocarbon derivatives, aromatics, and water vapor, while rejecting the non-condensable gases, such as methane, ethane, nitrogen, and hydrogen. The main applications are nitrogen removal, recovery of natural gas liquids, and dew-point control for associated natural gas and fuel gas conditioning for gas turbines and engines. There is also a membrane-based process for upgrading natural gas that contains C_{3+} hydrocarbon derivatives and/or acid gas is described. Mercaptans

A mercaptan (thiol) is a compound that contains the functional group composed of a sulfur atom and a hydrogen atom ($-SH$), being the sulfur analogue of an alcohol group ($-OH$). This sulfur-containing functional group is referred to either as a *thiol group* or a *sulphydryl group*. More traditionally, thiols are often referred to as *mercaptans*. Since sulfur and oxygen belong to the same periodic table group, they share some similar chemical bonding properties. Like alcohol, in general, the deprotonated form RS^- (thiolate) is more chemically reactive than the protonated thiol form (RSH).

Many thiols are colorless liquids having an odor that is often strong and objectionable, particularly the low-molecular-weight thiols.

Natural gas distributors add various forms of pungent thiols, usually ethanethiol (C_2H_5SH), to natural gas, which is naturally odorless, so that leaks can be easily detected. However, not all thiols have unpleasant odors. For example, grapefruit mercaptan, a monoterpenoid thiol, is responsible for the characteristic scent of grapefruit.

Thiols have lower boiling points than the corresponding alcohols and are less soluble in water and other polar solvents than alcohols of similar molecular weight. The S-H bond in the thiols has a lower dipole moment as compared to the O-H bond. Thiols show little association by hydrogen bonding, with both water molecules and among themselves. As a result, thiols are as soluble and have similar boiling points to the less polar isomeric sulfides.

The methods used in making thiols are analogous to those used to make alcohols and ethers. Thus, thiols are formed when a halogeno-alkane is heated with a solution of sodium hydrosulfide when heated in aqueous ethanol:

In addition, disulfides can be readily reduced by reducing agents such as lithium aluminum hydride in dry ether to form two thiols derivatives. Thus:

The chemistry of thiols is thus related to the chemistry of alcohols: thiols form thioethers, thioacetals, and thioesters, which are analogous to ethers, acetals, and esters. Furthermore, a thiol group can react with an alkene (olefin) to create a thioether.

The sulfur atom of a thiol is nucleophilic and, in the presence of a base, a thiolate anion is formed. The group and its corresponding anion are readily oxidized by reagents such as bromine to give an organic disulfide:

Oxidation by more powerful reagents such as sodium hypochlorite or hydrogen peroxide yield sulfonic acids (RSO_3H):

Mercury

Mercury, also called quicksilver, is a heavy, silvery metal that is one of six chemical elements that are liquid at or near-liquid at room temperature and pressure. With a melting point of -38.8°C (-37.9°F) and a boiling point of 356.7°C (674.1°F), mercury has one of the widest ranges of its liquid state of any metal.

Mercury occurs in deposits throughout the world mostly as cinnabar (mercuric sulfide, HgS), which is the source of the red pigment vermilion, and is mostly obtained by reduction from cinnabar. Cinnabar is highly toxic by ingestion or inhalation of the dust, and mercury poisoning can also result from exposure to soluble forms (such as mercuric chloride, HgCl_2 , or methylmercury, CH_3HgCH_3), inhalation of mercury vapor, or eating fish contaminated with mercury.

Mercury has been identified as a dangerous environmental contaminant, largely by reason of the process of concentration in the food chain. Thus, the presence of mercury in coal is an extremely sensitive issue. The possible emission of mercury that may be found in coal is an environmental concern.

Mercury is a common trace contaminant in natural gas, natural gas liquids, and other hydrocarbon sources. Mercury can be present in hydrocarbon derivatives in the form of ionic mercury species, organic mercury compounds, and metallic mercury. Mercury problems can be related to its toxicity (exposure during maintenance and inspection) and to the properties of the liquid metal regarding corrosion by embrittlement of sensitive alloys.

The solubility of mercury in hydrocarbon derivatives depends on the species involved, temperature, and the type of hydrocarbon derivatives. In addition, mercury can be converted from one species to another during various refinery processes. Mercury can be removed from hydrocarbon feedstocks or products by a number of processes, but the mercury species must be known for the most effective method to be employed.

Regenerative mercury removal adsorbents not only dry these streams but also remove mercury to less than 0.01 micrograms per normal cubic meter. Since the sorption sites for mercury removal are separate from and additive to the dehydration sites, mercury removal is accomplished by replacing a portion of the dehydration grade molecular sieve with specific adsorbents. The dryer bed size does not have to be increased to remove both water and mercury.

Molecular sieve products that contain silver on the outside surface of the molecular sieve pellet or bead. Mercury from the process fluid (either gas or liquid) amalgamates with the silver, and a mercury-free dry process fluid is obtained. Adding a layer of one of the adsorbents to an existing dryer results in the removal of both the design water

load and the mercury without requiring a larger dryer. Mercury and water are both regenerated from the adsorbents using conventional gas dryer techniques.

Meson

A meson is a subatomic particle composed of an equal number of quarks and antiquarks (usually one of each) that are bound together by strong interactions. A meson has a meaningful physical size, a diameter on the order of one femtometer (1×10^{-15} meter), which is approximately 1.2 times the size of a proton or neutron. All mesons are unstable, with the longest-lived lasting for only a few hundredths of a microsecond. Charged mesons decay (sometimes through mediating particles) to form electrons and neutrinos. An uncharged meson may decay to a photon.

See also: Electron, Muon, Neutrino, Photon.

Mesosphere

The mesosphere forms the top-most layer of the homosphere. The absence of high levels of radiation-absorbing species in the mesosphere (the third layer of the atmosphere, directly above the stratosphere and directly below the thermosphere) immediately above the stratosphere results in a further temperature decrease to approximately -92°C (-134°F) at an altitude ca. 53 miles (ca. 85 km). The upper regions of the mesosphere define a region (the exosphere) from which molecules and ions can completely escape the atmosphere. Extending to the far outer reaches of the atmosphere is the thermosphere, in which the highly rarified gas reaches temperatures as high as $1,200^{\circ}\text{C}$ ($2,200^{\circ}\text{F}$) by the absorption of very energetic radiation of wavelengths less than approximately 500 nanometers (nm) by gas species in this region.

Air temperatures in the mesosphere decrease upward to a minimum of -90°C at the mesopause, the boundary with the overlying thermosphere. The upper mesosphere is the second temperature minima in the atmosphere.

Metal Oxide Processes

These processes scavenge hydrogen sulfide and organic sulfur compounds (mercaptans) from gas streams through reactions with solid-based media. They are typically non-regenerable, although some are partially regenerable, losing activity upon each regeneration cycle. Most dry sorption processes are governed by the reaction of a metal oxide with hydrogen sulfide to form a metal sulfide compound. For regenerable reactions, the metal sulfide compound can then react with oxygen to produce elemental sulfur and a regenerated metal oxide. The primary metal oxides used for dry sorption processes are iron oxide and zinc oxide.

Dry sorption processes can be categorized into two subgroups: oxidation to sulfur and oxidation to oxides of sulfur. Because these processes rely on oxidation, gas constituents that cannot be oxidized under the process conditions will not be removed. This is advantageous when dealing with biogas, as only hydrogen sulfide, mercaptans, and, in some cases, carbon dioxide will be removed, with miniscule losses of methane due to adsorption. The main product of sulfur oxidation to oxides of sulfur is sulfur dioxide. Because this is a controlled exhaust gas, poses a threat to equipment due to corrosion and poisoning of fuel cell membranes, and requires additional gas processing to achieve air discharge standards, it will not be addressed as a gas processing option.

Generally, the iron oxide process is suitable only for small-to-moderate quantities of hydrogen sulfide. Approximately 90% of the hydrogen sulfide can be removed per bed, but bed clogging by elemental sulfur occurs and the bed must be discarded and the use of several beds in series is not usually economical. Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the Ferrox process or the Stretford process. The Ferrox process is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

Methanation

Methanation is the conversion of carbon monoxide and carbon dioxide (CO_x) to methane (CH_4) through by means of hydrogenation. The process is a means of carbon oxide removal from process gases. Methanation is also a means of producing synthetic natural gas (SNG, methane).

In wet scrubbing plants, the final hydrogen purification procedure involves is by methanation in which the carbon monoxide and carbon dioxide are converted to methane:

The active agent is nickel, on an alumina carrier. The catalyst has a long life, as it operates under ideal conditions and is not exposed to poisons. The main source of deactivation is plugging from carry-over of carbon dioxide from removal solutions.

The most severe hazard arises from high levels of carbon monoxide or carbon dioxide that can result from breakdown of the carbon dioxide removal equipment or from exchanger tube leaks that quench the shift reaction. The results of breakthrough can be severe, since the methanation reaction produces a temperature rise of 70°C (125°F) per 1% of carbon monoxide or a temperature rise of 33°C (60°F) per 1% of carbon dioxide. While the normal operating temperature during methanation is approximately 315°C (600°F), it is possible to reach 700°C ($1,300^\circ\text{F}$) in cases of major breakthrough.

See also: Methanation Catalysts.

Methanation Catalysts

The current technology for upgrading biogas focuses on removing carbon dioxide from the biogas. However, the biogas could potentially be used directly as feed gas for the Sabatier reaction, thereby removing the cost associated with carbon dioxide removal and increasing the methane yield and carbon utilization from biological sources. Carbon dioxide methanation requires a catalyst to be active at relatively low temperatures and selective toward methane. Nickel-based catalysts are most widely investigated, and commercial catalysts are typically nickel on alumina support. Focus on catalyst development for carbon dioxide methanation is predominantly related to support modification, promoter addition, as well as utilizing new class of materials such as hydrotalcite-derived catalysts.

In wet scrubbing plants, the final hydrogen purification procedure involves methanation in which the carbon monoxide and carbon dioxide are converted to methane. The active agent is nickel, on an alumina carrier.

Methane

Methane (CH₄) is the simplest alkane. It is gaseous and the principal component of natural gas. Combustion of methane produces carbon dioxide and water. At room temperature and pressure, methane is a colorless, odorless gas. The smell characteristic of natural gas as used in homes is an artificial safety measure caused by the addition of an odorant, often methanethiol (CH₃SH) or ethanethiol (C₂H₅SH). Methane has a boiling point of -161°C (-258°F) at a pressure of one atmosphere (Table M-1). As a gas, methane is flammable only over a range of concentrations (5 to 15% v/v) in air. Liquid methane does not burn unless subjected to high pressure (normally 60 to 70 psi, 4 to 5 atmospheres).

Table M-1 Boiling point and density of methane relative to air and water.

• Boiling Point (760 mm Hg): -161.5°C (-258.7°F)
• Gas Specific Gravity: 0.55 to 0.64 (air = 1.00)
• Specific Gravity of Liquefied Natural Gas: 0.42 to 0.46 (water = 1.00)
• Gas Density (varies slightly): 0.0438 lb/scf

The relative abundance of methane makes it an attractive fuel, and, in its natural gas form, it is generally transported in bulk by pipeline or LNG carriers. However, methane is a relatively potent greenhouse gas and in the atmosphere is eventually oxidized, producing carbon dioxide and water.

Large amounts of methane are produced anaerobically by methanogenesis. Other sources include mud volcanoes, which are connected with deep geological faults, landfill, and livestock (primarily ruminants) from enteric fermentation.

In the combustion of methane, several steps are involved: methane forms formaldehyde (HCHO) to produce a formyl radical (HCO), which then forms carbon monoxide (CO):

Following oxidative pyrolysis, the hydrogen oxidizes, forming water:

Finally, the carbon monoxide oxidizes, forming carbon dioxide:

Thus:

Methane is important for electrical generation by combustion as a fuel in a gas turbine or steam boiler. In many cities, methane (natural gas) is piped into homes for domestic heating and cooking purposes.

Methane is used in industrial chemical processes and may be transported as a refrigerated liquid (liquefied natural gas, or LNG). While leaks from a refrigerated liquid container are initially heavier than air due to the increased density of the cold gas, the gas at ambient temperature is less dense (lighter) than air.

In the chemical industry, methane is the feedstock of choice for the production of hydrogen, methanol, acetic acid, and acetic anhydride. When used to produce any of these chemicals, methane is first converted to synthesis gas, a mixture of carbon monoxide and hydrogen, by steam reforming. In this process, methane and steam react on a nickel catalyst at high temperatures (700–1,100 °C).

The ratio of carbon monoxide to hydrogen in synthesis gas can then be adjusted via the water gas shift reaction to the appropriate value for the intended purpose.

Less significant methane-derived chemicals include acetylene, prepared by passing methane through an electric arc, and the chloromethanes (chloromethane, dichloromethane, chloroform, and carbon tetrachloride), which are produced by reacting methane with chlorine gas. However, the use of these chemicals is declining. Acetylene is replaced by less costly substitutes, and the use of chloromethanes is diminishing due to health and environmental concerns.

Methane Number

The methane number is a measure of the resistance of natural gas to detonation when it is burned as a motor fuel in an engine. Pure methane is assigned a methane number of 100, and pure hydrogen is assigned a methane number of zero. A natural gas having a methane number of 80 for example, would have the detonation properties of a mixture consisting of 80 vol% methane and 20 vol% hydrogen. The methane number concept is similar to the octane number for gasoline. Unlike gasoline however, there is not yet a universal standard for testing natural gas methane number as there is in the motor test for gasoline. Also, there is no universally accepted method for calculating the methane number based on the composition of natural gas.

The definition of the methane number is simple if the gas consists only of the two components methane and hydrogen. But for hydrocarbon gas mixtures consisting not only of methane but also of ethane and heavier, the definition is much more difficult and is the subject of much debate and controversy. There are various proposed methods of calculating the methane number based on gas composition. Some are methods proposed by standards associations in Europe, and some are proprietary methods proposed by engine manufacturers.

Methanogenesis

Methanogenesis is the terminal phase of anaerobic digestion in which methanogens use the intermediate products of the preceding phases and convert them to them into methane, carbon dioxide, and water. These components make up the majority of the biogas emitted from the system.

Two different groups of bacteria are responsible for the methane production. One group degrades acetic acid to methane, and the other produces methane from carbon dioxide and hydrogen. Under stable conditions, the majority (approximately 70% v/v) of the methane production comes from the degradation of acetic acid, while the remaining methane production (approximately 30% v/v) comes from carbon dioxide and hydrogen. The two processes are balanced, and inhibition of one will also lead to inhibition of the other. The methanogens have the slowest growth rate of the bacteria involved in the process; they also become the limiting factor for how quickly the process can proceed and how much material can be digested.

Methanogenesis is sensitive to both high pH (alkaline) and low pH (acidic) and occurs between pH 6.5 and pH 8, in near neutral conditions. The remaining, indigestible material the microbes cannot use, and any dead bacterial remains constitute the digestate.

Methane-producing bacteria decompose compounds with a low molecular weight. For example, they utilize hydrogen, carbon dioxide, and acetic acid to form methane and carbon dioxide. Under natural conditions, methane-producing microorganisms occur to the extent that anaerobic conditions are provided, e.g., under water (for example in marine sediments), in ruminant stomachs and in marshes. They are obligatory anaerobic and sensitive to environmental changes. In contrast to the acidogenic and acetogenic bacteria, the methanogenic bacteria belong to the archaeobacter genus, i.e., to a group of bacteria with a very heterogeneous morphology and a number of common biochemical and molecular-biological properties that distinguish them from all other bacterial general. The main difference lies in the makeup of the bacteria's cell walls.

In the overall process, the acid-producing bacteria and the methane-producing bacteria act in a symbiotic way. On the one hand, acid-producing bacteria create an atmosphere with ideal parameters for methane-producing bacteria (anaerobic conditions, compounds with a low-molecular-weight feedstock). On the other hand, methane-producing microorganisms use the intermediates of the acid-producing bacteria. Without removal (consumption) of these intermediate products from the system by the methane-producing microorganisms, toxic conditions for the acid-producing microorganisms would develop leading to an inhibition effect and a loss of process efficiency.

Essentially, the four phases of anaerobic degradation take place simultaneously in a single-phase process. However, as the bacteria involved in the various phases of degradation have different requirements in terms of habitat (regarding pH value and temperature, for example), a compromise has to be found in the process technology. Since the methanogenic microorganisms are the weakest link in the four phases because of the low rate of growth of the methanogens and they are the most sensitive to respond to disturbances, the digester conditions have to be adapted to the requirements of the methane-forming bacteria. However, any attempt to physically separate hydrolysis and acidogenesis from methanogenesis by implementing two distinct process phases (two-phase process management) will succeed to only a limited extent because, despite the low pH value in the hydrolysis phase ($\text{pH} < 6.5$), some methane will still be formed. The resulting hydrolysis gas therefore also contains methane in addition to carbon dioxide and hydrogen. In multi-phase processes, different environments can become established in the individual digester phases depending on the design of the biogas plant and its operating regime, as well as on the nature and concentration of the fresh mass used as substrate. In turn, the ambient conditions affect the composition and activity of the microbial biocoenosis and thus have a direct influence on the resulting metabolic products.

As a recap, Phase 1 of the process is the hydrolysis reaction in which high-molecular-weight naturally-occurring compounds (cellulose, hemicellulose, and lignin) are converted to lower-molecular-weight products. Typically sugars and oxygenated aromatic derivatives. During acidogenesis, soluble monomers are converted into small organic compounds, such as short chain (volatile) acids (propionic, formic, lactic, butyric, succinic acids), ketones (glycerol, acetone), and alcohols (ethanol, methanol). Generally, the chemistry of Phase 2 (acidogenesis) and Phase 3 (acetogenesis) can be represented by a series of simple equations:

Acidogenesis:

Acetogenesis:

Phase IV is the phase of methane formation (methanogenesis) in which the concentrations of the intermediate acids are small in proportion to their production and degradation rates, and they are quickly transformed to methanogenic substrates, including acetate, methanol, and formate. Thus, the last phase of anaerobic digestion is the methanogenesis phase. Several reactions take place using the intermediate products from the other phases, with the main product being methane. The reactions are commonly represented as:

Several bacterial contribute to methanogenesis, including: Methanobacterium, methanobacillus, methanococcus, and methanosarcina.

Any kind of organic matter can be fed to an anaerobic digester, including manure and litter, food wastes, green wastes, plant biomass, and wastewater sludge. The materials that compose these feedstocks include polysaccharides, proteins, and fats/oils. Some of the organic materials degrade at a slow rate; hydrolysis of cellulose and hemicellulose is rate limiting (Amani et al., 2010). There are some organic materials that do not biodegrade: lignin, peptidoglycan (a polymer consisting of sugar derivatives and amino acid derivatives that forms a mesh-like layer outside the plasma membrane of most bacteria, forming the cell wall), and membrane-associated proteins. The organic residues contain water and biomass composed of volatile solids and fixed solids (minerals or ash after combustion), and it is the volatile solids that can be non-biodegradable and biodegradable. However, unlike the chemistry of the anaerobic digester, the organic waste in the landfill is not available for separate pretreatment unless there is a form of pretreatment before the material is discharged into the landfill.

Methanogens

Methanogens are methane-producing microorganisms that are usually coccoid (spherical) or bacilli (rod shaped). They are anaerobic organisms and cannot function under aerobic conditions, being sensitive to the presence of oxygen even at trace levels. Some methanogens (hydrogenophobic organisms) use carbon dioxide (CO_2) as a source of carbon, and hydrogen as a reducing agent:

Methanogens typically thrive in environments in which all electron acceptors other than carbon dioxide (such as oxygen, nitrate, trivalent iron, and sulfate) have been depleted. Methanogens are key agents of remineralization of organic carbon in sediments on continental margins and other aquatic sediments with high rates of sedimentation and high sediment organic matter. Under the correct conditions of pressure and temperature, biogenic methane can accumulate in massive deposits of methane clathrates (methane hydrates), which account for a significant fraction of organic carbon in continental margin sediments and represent a key reservoir of a potent greenhouse gas.

Closely related to the methanogens are the anaerobic methane oxidizers, which utilize methane as a substrate in conjunction with the reduction of sulfate and nitrate. Most methanogens are autotrophic producers, but those that oxidize acetate (CH_3COO^-) are classed as chemotrophic producers.

Methanol

Methanol (CH_3OH ; methyl alcohol; wood alcohol, wood naphtha, wood spirits) is a colorless, volatile, inflammable, and poisonous alcohol traditionally formed by destructive distillation of wood or, more recently, as a result of synthetic distillation in chemical plants. It is the simplest alcohol, and is a low-boiling, volatile, colorless, flammable, poisonous liquid with a distinctive odor that is somewhat milder and sweeter than ethanol (ethyl alcohol). At room temperature, methanol is a polar liquid and is used as an antifreeze, solvent, fuel, and as a denaturant for ethyl alcohol. It is also used for producing biodiesel via transesterification reaction.

Methanol is a colorless, odorless, and nearly tasteless alcohol and is also produced from crops and is also used as a fuel. Methanol, like ethanol, burns more completely but releases as much or more carbon dioxide than its gasoline counterpart. The balance is often seen as the various bi-processes that draw carbon dioxide from the atmosphere so there is no net modern release, as there is for fossil fuels.

Pyrolysis (heating wood in the absence of air) to a temperature above 270°C (520°F) in a retort causes thermal cracking or breakdown of the wood and allows much of the wood to be recovered as charcoal. The watery condensate leaving the retort contained methanol, among other compounds.

Methods proposed for the production of methanol from biomass involve the conversion of the biomass to synthesis gas, after which the processing steps are similar to those developed for methanol from natural gas. However, before biomass can be gasified, it must be pre-treated to meet the processing constraints of the gasifier. This typically involves size reduction, and drying to keep moisture contents below specific levels. Thereafter, biomass gasification involves heating biomass in the presence of low levels of oxygen (i.e., less than required for complete combustion to carbon dioxide and water). Above certain temperatures, the biomass will break down into a gas stream and a solid residue. The composition of the gas stream is influenced by the operating conditions for the gasifier, with some gasification processes more suited than others to producing a gas for methanol production. In particular, simple gasification with air creates a synthesis gas stream that is diluted with large quantities of nitrogen. This nitrogen is detrimental to subsequent processing to methanol, and so techniques using indirect gasification or an oxygen feed are preferred.

Methanol burns in air forming carbon dioxide and water:

A methanol flame is almost colorless, causing an additional safety hazard around open methanol flames.

Because of its poisonous properties, methanol is frequently used as a denaturant additive for ethanol manufactured for industrial uses – this addition of a poison economically exempts industrial ethanol from the rather significant liquor taxes that would otherwise be levied as it is the essence of all potable alcoholic beverages. Methanol is often called wood alcohol because it was once produced chiefly as a by-product of the destructive distillation of wood. It is now produced synthetically by a multi-step process: natural gas and steam are reformed in a furnace to produce hydrogen and carbon monoxide; then, hydrogen and carbon monoxide gases react under pressure in the presence of a catalyst.

The use of methanol as a motor fuel received attention during the oil crises of the 1970s due to its availability and low cost. Problems occurred early in the development of gasoline-methanol blends. As a result of its low price, some gasoline marketers over-blended. Others used improper blending and handling techniques.

Synthesis gas is most commonly produced from the methane component in natural gas rather than from coal. Three processes are commercially practiced. At moderate pressures (of 150 to 300 psi) and high temperatures (around 850°C), methane reacts with steam on a nickel catalyst to produce synthesis gas:

This reaction, commonly called steam-methane reforming, is endothermic, and the heat transfer limitations place limits on the size of and pressure in the catalytic reactors used.

Methane can also undergo partial oxidation with molecular oxygen to produce synthesis gas:

This reaction is exothermic, and the heat given off can be used in-situ to drive the steam-methane reforming reaction. When the two processes are combined, it is referred to as autothermal reforming. The ratio of carbon dioxide to hydrogen can be adjusted to some extent by the water-gas shift reaction:

This reaction provides the appropriate stoichiometry for methanol synthesis. The carbon monoxide and hydrogen then react on a second catalyst to produce methanol. The most widely used catalyst is a mixture of copper, zinc oxide, and alumina (at 50 to 100 atmospheres and 250°C, 480°F) which catalyzes the production of methanol from carbon monoxide and hydrogen with high selectivity:

The production of synthesis gas from methane produces 3 moles of hydrogen for every mole of carbon monoxide, while the methanol synthesis consumes only 2 moles of hydrogen for every mole of carbon monoxide. One way of dealing with the excess hydrogen is to inject carbon dioxide into the methanol synthesis reactor, where it, too, reacts to form methanol:

The largest use of methanol by far, is in making other chemicals. Approximately 40% of methanol is converted to formaldehyde, and from there into products as diverse as plastics, plywood, paints, explosives, and permanent press textiles. One of the drawbacks of methanol as a fuel is its corrosivity to some metals, including aluminum. Methanol, although a weak acid, attacks the oxide coating that normally protects the aluminum from corrosion:

The resulting methoxide salts are soluble in methanol, resulting in clean aluminum surface, which is readily oxidized by some dissolved oxygen. Also, the methanol can act as an oxidizer:

This reciprocal process effectively fuels corrosion until either the metal is eaten away or the concentration of methanol is negligible.

When produced from wood or other organic materials, the resulting organic methanol (bioalcohol) has been suggested as renewable alternative to petroleum-based hydrocarbon derivatives. However, one cannot use pure methanol in modern petroleum cars without modification, due to potential damage to metal piping and rubber seals.

Methanol is a traditional denaturant for ethanol, thus giving the term methylated spirit. Methanol is also used as a solvent, and as antifreeze in pipelines and windshield washer fluid. In some wastewater treatment plants, a small amount of methanol is added to wastewater to provide a food source of carbon for the denitrifying bacteria, which convert nitrates to nitrogen.

Methanol is probably one of the most versatile solvents in the natural gas processing industry. Historically, methanol was the first commercial organic physical solvent and has been used for hydrate inhibition, dehydration, gas sweetening, and liquids recovery. Most of these applications involve low temperature where the physical properties of methanol are advantageous compared with other solvents that exhibit high viscosity problems or even solids formation. Operation at low temperatures tends to suppress the most significant disadvantage of using methanol, i.e., high solvent loss.

Methanol has favorable physical properties relative to other solvents except for vapor pressure. The benefits of the low viscosity of methanol at low temperature are manifested in the pressure drop improvement in the cold box of injection facilities and improved heat transfer. Methanol has a much lower surface tension relative to the other solvents. High surface tension tends to promote foaming problems in contactors. Methanol processes are probably not susceptible to foaming. However, the primary drawback of methanol is the high vapor pressure that is several times

greater than that of the glycols or amines. To minimize methanol losses and enhance water and acid gas absorption, the absorber or separator temperatures are usually less than -29°C (-20°F).

The high vapor pressure of methanol may initially appear to be a significant drawback because of high solvent losses. However, the high vapor pressure also has significant advantages. Although often not considered, lack of thorough mixing of the gas and solvent can pose significant problems. Because of the high vapor pressure, methanol is completely mixed in the gas stream before the cold box. Glycols, because they do not completely vaporize, may require special nozzles and nozzle placement in the cold box to prevent freeze-up. Solvent carry-over to other downstream processes may also represent a significant problem. Since methanol is more volatile than glycols, amines, and other physical solvents including lean oil, methanol is usually rejected in the regeneration step of these downstream processes. The stripper concentrates the methanol in the overhead condenser where it can be removed and further purified. Unfortunately, if glycols are carried over to amine units, the glycol becomes concentrated in the solution and potentially starts to degrade and possibly dilute the amine solution.

Methanol has been extensively used as a hydrate inhibitor, but predicting the behavior of methanol is complicated and, in fact, the thermodynamic properties and phase equilibrium of mixtures of methanol, water, and hydrocarbon derivatives are notoriously difficult to predict. Methanol shows both polar and non-polar characteristics. Consequently, these characteristics give methanol the unique ability to be used in an extensive range of applications.

Methanol – Production

Methanol and other chemicals were routinely extracted from wood in the 19th and early 20th centuries. However, the original route for methanol recovery from biomass was quite different to current routes. Methanol was originally recovered from wood as a by-product of charcoal manufacture, and was often called “wood alcohol.” Pyrolysis (heating wood in the absence of air) to above 270°C in a retort causes thermal cracking or breakdown of the wood and allows much of the wood to be recovered as charcoal. In 1923, commercial production of methanol from synthesis gas by a catalytic process was commenced. Currently, almost all of the methanol used worldwide comes from the processing of natural gas.

Methanol is manufactured from natural gas by a steam reforming process. Methane of natural gas is first mixed with steam at 3/1 ratio. It is then reformed to carbon oxides and hydrogen under nickel catalyst at 1000°C (1830°F) and 20 atmospheres. Carbon oxides and hydrogen reacts exothermically at approximately 70 atmospheres pressure in the gas phase to form mainly methanol and water mixture. These reactions take place in the presence of Cu, Al, and Zn-based catalyst. Crude methanol is cooled and condensed and fed through a distillation process to achieve a product purity of 99.9 mole%. As an alternative, partial oxidation or oxygen aided processes are also used.

As with any fuel, methanol production economics are highly dependent on the feedstock selection and feedstock prices. Methanol can be manufactured from any hydrocarbon source such as: naphtha, oil, coal, wood, bio-mass, and LPG. The naphtha – a fraction from crude oil distillation – is used as a raw material in many older facilities for the manufacture of methanol.

In general, methanol production from natural gas feed consists of three steps which are (i) synthesis gas (syngas) generation – in the case of natural gas feed, synthesis gas production consists of converting methane (CH_4) into carbon monoxide (CO) and hydrogen (H_2) via steam reforming, (ii) synthesis gas upgrading – primarily removal of CO_2 , plus any contaminants such as sulfur, and (iii) methanol synthesis and purification – reacting the carbon monoxide, hydrogen, and steam over a catalyst in the presence of a small amount of CO_2 and at elevated temperature and pressure. The methanol synthesis is an equilibrium reaction, and excess reactants must be recycled to optimize yields.

Modern methods proposed for the production of methanol from biomass involve the conversion of the biomass to a suitable synthesis gas, after which the processing steps are similar to those developed for methanol from natural gas. However, the gasification techniques proposed are still at a relatively early stage of development using biomass feed and the methods are based on similar techniques used widely already with natural gas as feed.

Before biomass can be gasified, it must be pre-treated to meet the processing constraints of the gasifier. This typically involves size reduction, and drying to keep moisture contents below specific levels. Thereafter, biomass gasification involves heating biomass in the presence of low levels of oxygen (i.e., less than required for complete combustion to carbon dioxide and water). Above certain temperatures, the biomass will break down into a gas stream and a solid residue.

The composition of the gas stream is influenced by the operating conditions for the gasifier, with some gasification processes more suited than others to producing a gas for methanol production. In particular, simple gasification with air creates a synthesis gas stream that is diluted with large quantities of nitrogen. This nitrogen is detrimental to subsequent processing to methanol, and so techniques using indirect gasification or an oxygen feed are preferred. For large-scale gasification, pressurized systems are considered to be more economic than atmospheric systems.

Once the economic optimum synthesis gas is available, the methanol synthesis takes place. This typically uses a copper-zinc catalyst at temperatures of 200 to 280°C (390 to 540°F) and pressures of 50 to 100 atmospheres.

The crude methanol from the synthesis loop contains water produced during synthesis as well as other minor by-products. Purification is achieved in multistage distillation, with the complexity of distillation dictated by the final methanol purity required.

Methanol – Properties

Methanol (methyl alcohol, carbinol, methyl hydroxide, methylol, monohydroxy methane, wood alcohol, colonial spirit, hydroxy methane, wood naphtha) has properties that are consistent with the low molecular weight but also consistent with the ability of the molecule to form intermolecular hydrogen bonds (Table M-2).

Table M-2 Selected properties of methanol compared to ethanol.

Property	Methanol	Ethanol
	CH₃OH	C₂H₅OH
Molecular weight	32	46
Specific gravity	0.789 (298 K)	0.788 (298 K)
Vapor density relative to air	1.10	1.59
Liquid density (g cm ⁻³ at 25°C)	0.79	0.79
Boiling point (°C)	65	78
Melting point (°C)	-98	-144
Vapor pressure @ 100°C (psia)	4.6	2.5
Heat of evaporation (Btu/lb)	472	410
Heating value (kBtu per gallon)		
Lower	58	74
Upper	65	85
Viscosity (cp)	0.54	1.20
Flash point (K)	284	287
Flammability/explosion limits		
- (%) Lower (LFL)	6.7	3.3
- (%) Upper (UFL)	36	19
Auto ignition temperature (K)	733	636
Solubility in water (%)	Miscible(100%)	Miscible (100%)
Azeotrope with water	None	95% v/v EtOH

The density of methanol at room temperature, at 25°C, is 0.7918 g/cm³. The heat of formation for methanol as gas ($\Delta H^\circ_{f,\text{gas}}$) is -201.1 ± 0.2 kJ/mol, whereas that for the liquid methanol ($\Delta H^\circ_{f,\text{liquid}}$) is -239.5 ± 0.2 kJ/mol. The constant-pressure heat capacity of methanol as gas ($C_{p,\text{gas}}$) at room temperature is 44 J/°K-mol, while that for liquid methanol is 80 ± 1 J/°K-mol. The Henry's law constant (K_H) for solubility of methanol in water at 298.15 °K is 210 ± 10 mol/kg-bar.

The critical temperature and pressure of methanol are 513 ± 1.2 °K and 81 ± 1.0 bars, respectively, while the normal boiling and melting temperatures are 337.8 ± 0.3 °K and 176.0 ± 1.0 °K, respectively. The triple point of methanol is 175.5 ± 0.5 °K. The flash point of methanol is 11°C. The enthalpy of vaporization of methanol at room temperature ($\Delta H^\circ_{\text{vap}}$) is 37.83 kJ/mol². Methanol can be used as a supercritical solvent or co-solvent for a variety of modern processes. The hydroxyl group in its molecular structure renders unique properties that are normally not attained from carbon dioxide. Its critical point is harsher than carbon dioxide, but milder than water.

The acidity of methanol is $\text{pK}_a = \sim 15.5$ and viscosity is 0.54 cP at 20°C (68°F). Due to its low freezing point, methanol has been popularly used as a cold-weather windshield washer fluid. A concentration of 30% by wt. can provide anti-freezing protection of -20°C (-4°F). Due to the hydroxyl group in methanol, it has a strong tendency of hydrogen bonding. A hydrogen bond is not a true bond, but a particularly strong form of dipole-dipole interaction. The hydroxyl (O-H) bonds are strongly polarized, thus leaving the hydrogen atom with a partially positive charge, which is electrophilic hydrogen. This hydrogen has a strong affinity for nonbonding electrons, and as such, it forms intermolecular attachments with the nonbonding electrons on oxygen atom. Comparing the two isomers between ethanol (C₂H₅OH) and dimethyl ether (CH₃OCH₃), both of which have a formulation of C₂H₆O, one can immediately notice that ethanol has much higher boiling point (78°C, 172°F) than that of dimethyl ether (-25°C, 13°F). This striking difference of approximately 100°C (180°F) in the respective boiling points is due to the fact that ethanol has hydroxyl (O-H) hydrogen which is extensively hydrogen-bonded, whereas dimethyl ether has no hydroxyl hydrogen, thus without the benefit of hydrogen bonding.

Methanol also reacts easily with carboxylic acids to produce esters from which water is a by-product of condensation type of reaction. The presence of methyl group in the formula provides chemical affinity toward hydrocarbon derivatives, and as such, methanol shows excellent solubility toward a variety of organic materials, while the presence of hydroxyl group renders excellent water miscibility. The dual nature of the solubility makes methanol as a good candidate for oxygenate fuel as well as water remover from gasoline. As a water remover in a gasoline fuel system, presence of methanol in the formulation creates a miscible ternary mixture (gasoline-methanol-water) instead of an immiscible binary mixture (gasoline-water).

Methanol has an octane rating of 105 (Research Octane Number, RON) and can be used as an octane enhancer. Since high performance with a higher compression ratio requires a higher octane rating than its regular counterparts, methanol is used as a racing fuel. Due to the high oxygen content (50% by mass) in the methanol molecular structure, it appears to be an excellent oxygenate fuel. However, it should be noted that its blending vapor pressure increase is substantially higher than other competing oxygenate blends such as MTBE (methyl-t-butyl ether) and ethanol, thus making it unpopular as a gasoline blending fuel. The vapor pressure increase due to gasoline blending is typically measured by Reid vapor pressure. The high vapor pressure of blended gasoline can increase the chance for evaporative emission of the fuel as well as the risk of having "vapor lock" in the fuel line. Furthermore, the toxicity of methanol, if inhaled or internally taken, is far more serious than that of ethanol. Evaporative fuel emission is particularly of concern to environmental air quality during summer months, when the emitted hydrocarbon is linked with the environmental health problem of "high ozone level in the air."

The common method for measuring the vapor pressure of crude oil products is the Reid vapor pressure test, or RVP test. There are basically two methods approved also by ASTM, i.e., Reid method (ASTM D323) and dry method (ASTM D4953). The Reid method covers experimental measurements of vapor pressure of gasoline, volatile crude oil, and other volatile crude oil products that include crude oil crude, gasoline, MTBE-blended gasoline, aviation fuel, and other crude oil products. There are four procedures provided by this method, depending upon the types and vapor pressure ranges of the tested fuel. However, this method is not applicable to liquefied crude oil gas (LPG) and oxygenated gasoline except MTBE-blended gasoline.

For the determination of the vapor pressure of liquefied crude oil gases (LPG), ASTM D1267 is the recommended test method whereas determination of the vapor pressure of gasoline-oxygenate blends refers to ASTM D4953. The

latter method is referred to as the dry method, which is applicable to most oxygenated gasolines, except MTBE-blended gasoline, with a vapor pressure range from 5 to 15 psi. There are thermodynamic algorithms developed for estimation of RVP without performing actual measurement.

Methanol – Reactions

Pure methanol is an important material in chemical synthesis. Its derivatives are used in great quantities for building up a vast number of compounds, among them many important synthetic dyestuffs, resins, drugs, and perfumes. Large quantities are converted to dimethyl aniline for dyestuffs and to formaldehyde for synthetic resins. It is also used in automotive antifreezes, in rocket fuels, and as a general solvent. Methanol is also a high-octane, clean-burning fuel that is a potentially important substitute for gasoline in automotive vehicles.

Methanol is used to produce formaldehyde via an oxidation reaction in which approximately 40% of methanol is converted to formaldehyde (HCHO), and from there into products as diverse as thermosetting polymers, plywood, paints, explosives, and permanent press textiles.

Methanol is also used for making a variety of ethers including MTBE (methyl-t-butyl ether), ETBE (ethyl-t-butyl ether), TAME (t-amyl-methyl ether), DME (dimethyl ether), etc. The first three are normally synthesized by catalytic distillation (CD), whereas the fourth is produced by catalytic dehydration. As the name implies, catalytic distillation is a hybrid process between a well-established unit operation of distillation and a catalytic chemical reaction. Methanol also readily reacts with carboxylic acids to produce methyl esters of these acids. These esters, in particular fatty acid esters, are quite important as ingredients for biodiesel, fuel additives, fuel system cleaners, octane enhancers, biodiesel formulations, etc.

Dimethyl ether (DME) is gaining extra significance as a renewable fuel. Dimethyl ether has always been considered a major derivative of methanol, and its synthesis is based on the following stoichiometric equation:

Methanol serves as a direct reactant or as an intermediate in the synthesis of dimethyl ether, depending upon the reaction routes.

The first process route is based on conventional dehydration of methanol over a dehydration catalyst, where methanol is a direct reactant and dimethyl ether and water are recovered as products. This process is carried out as a stand-alone type of process. In recent years, however, the second process option where methanol is an intermediate in the conversion of synthesis gas to dimethyl ether, i.e., single-stage synthesis of dimethyl ether from synthesis gas, has attracted a great deal of attention.

The process benefits have been two-fold, one being that the direct synthesis of dimethyl ether from synthesis gas can overcome the equilibrium limitation imposed by methanol synthesis reaction and the other being the reaction of converting methanol into dimethyl ether is an important precursor step for methanol-to-hydrocarbon conversion processes represented by the methanol-to-olefin process (MTO process) and the methanol-to-gasoline process (MTG process).

Even if dimethyl ether itself is considered a final product, the direct route via single-stage synthesis is far more advantageous from the standpoints of both production cost and process efficiency. The single-stage synthesis of dimethyl ether exploits the equilibrium-unlimited dehydration of methanol to dimethyl ether to its fullest extent by alleviating the equilibrium-limited nature of the methanol synthesis reaction. This is accomplished via a dual catalytic system in which in-situ produced methanol is selectively removed from the reaction equilibrium by converting the product methanol to dimethyl ether. In this process, methanol concentration in the reactor is being kept low, thus keeping the methanol synthesis portion of the overall conversion process far from its chemical equilibrium. Catalyst 1, such as $\text{Cu/ZnO/Al}_2\text{O}_3$, does the first reaction of methanol synthesis, whereas Catalyst 2, such as $\gamma\text{-Al}_2\text{O}_3$, catalyzes dehydration of methanol. Both reactions are carried out in the very same reactor, and therefore, such reaction system is called a dual catalytic system. Obviously, as an advantage, a higher once-through conversion of synthesis gas to dimethyl ether can be attained.

Direct methanol fuel cells (DMFC) are unique in their low temperature, atmospheric pressure operation, allowing them to be miniaturized to an unprecedented degree. This direct methanol fuel cell technology combined with the relatively easy and safe storage and handling of methanol may open the possibility of fuel cell-powered consumer electronics.

Methanol-Based Processes

Methanol has favorable physical properties relative to other solvents except for vapor pressure. The benefits of the low viscosity of methanol at low temperature are manifested in the pressure drop improvement in the cold box of injection facilities and improved heat transfer. Methanol has a much lower surface tension relative to the other solvents. High surface tension tends to promote foaming problems in contactors. Methanol processes are probably not susceptible to foaming. However, the primary drawback of methanol is the high vapor pressure that is several times greater than that of the glycols or amines. To minimize methanol losses and enhance water and acid gas absorption, the absorber or separator temperatures are usually less than -29°C (-20°F).

The high vapor pressure of methanol may initially appear to be a significant drawback because of high solvent losses. However, the high vapor pressure also has significant advantages. Although often not considered, lack of thorough mixing of the gas and solvent can pose significant problems. Because of the high vapor pressure, methanol is completely mixed in the gas stream before the cold box. Glycols, because they do not completely vaporize, may require special nozzles and nozzle placement in the cold box to prevent freeze-up. Solvent carry-over to other downstream processes may also represent a significant problem. Since methanol is more volatile than glycols, amines, and other physical solvents including lean oil, methanol is usually rejected in the regeneration step of these downstream processes. The stripper concentrates the methanol in the overhead condenser where it can be removed and further purified. Unfortunately, if glycols are carried over to amine units, the glycol becomes concentrated in the solution and potentially starts to degrade and possibly dilute the amine solution.

The use of methanol has been further exploited in the development of the Rectisol process either alone or as toluene-methanol mixtures are used to remove hydrogen sulfide and slip carbon dioxide to the overhead product more selectively. Toluene has an additional advantage insofar as carbonyl sulfide (carbonyl sulfide) is more soluble in toluene than in methanol. The Rectisol process was primarily developed to remove both carbon dioxide and hydrogen sulfide (along with other sulfur-containing species) from gas streams resulting from the partial oxidation of coal, oil, and petroleum residua. The ability of methanol to absorb these unwanted components made it the natural solvent of choice. Unfortunately, at cold temperatures, methanol also has a high affinity for hydrocarbon constituents of the gas streams. For example, propane is more soluble in methanol than is carbon dioxide. There are two versions of the Rectisol process – the two-stage and the once-through. The first step of the two-stage process is desulfurization before shift conversion; the concentrations of hydrogen sulfide and carbon dioxide are approximately 1 and 5% v/v, respectively. Regeneration of the methanol following the desulfurization of the feed gas produces high sulfur feed for sulfur recovery. The once-through process is only applicable for high pressure partial oxidation products. The once-through process is also applicable when the hydrogen sulfide to carbon dioxide content is unfavorable, in the neighborhood of 1:50.

Recently, a process using methanol has been developed in which the simultaneous capability to dehydrate, to remove acid gas, and to control hydrocarbon dew point. The IFPEXOL-1 is used for water removal and hydrocarbon dew point

control; the IFPEXOL-2 process is used for acid gas removal. The novel concept behind the IFPEXOL-1 process is to use a portion of the water-saturated inlet feed to recover the methanol from the aqueous portion of the low temperature separator. That approach has solved a major problem with methanol injection in large facilities, the methanol recovery via distillation. Beyond that simple discovery, the cold section of the process is remarkably similar to a basic methanol injection process. Modifications to the process include water washing the hydrocarbon liquid from the low temperature separator to enhance the methanol recovery. The IFPEXOL-2 process for acid gas removal is similar to an amine-type process except for the operating temperatures. The absorber operates below -20°F to minimize methanol losses, and the regenerator operates at approximately 90 psi. Cooling is required on the regenerator condenser to recover the methanol. This process usually follows the IFPEXOL-1 process, so excessive hydrocarbon absorption is not as great a problem.

Methanol-to-Gasoline Process

Methanol is produced catalytically from synthesis gas, and by-products such as ethers, formic acid esters, and higher-molecular-weight hydrocarbon derivatives are formed in side reactions and are found in the crude methanol product. Whereas for many years, methanol was produced from coal; after World War II, low-cost natural gas and low-boiling crude oil fractions replaced coal as the feedstock.

Following from this, one of the most significant developments in synthetic fuels technology since the discovery of the Fischer-Tropsch process is the Mobil methanol-to-gasoline (MTG) process (now the ExxonMobil methanol-to-gasoline process) in which methanol is efficiently transformed into hydrocarbon derivatives ranging from ethane to decane by a reaction that is catalyzed by synthetic zeolites.

Olefins and aromatic compounds are also produced, and the chemistry of the reaction is more complex than this simple equation illustrates. For accuracy and economics, chemical equations should be derived for each particular aspect of the process.

In the process (which can use a fixed bed reactor or a fluid bed reactor), the methanol feed, vaporized by heat exchange with reactor effluent gases, is converted in a first-stage reactor containing an alumina catalyst to an equilibrium mixture of methanol, dimethyl ether, and water. This is combined with recycle low-boiling gas, which serves to remove reaction heat from the highly exothermic methanol-to-gasoline reaction, and enters the reactors containing zeolite catalyst, and reaction conditions are 360 to 415°C (680 to 780°F) at a pressure of approximately 300 to 350 psi.

Because the methanol-to-gasoline process produces primarily gasoline, a variation of that process has been developed which allows for production of gasoline and distillate fuel. The combined process (methanol-to-olefins and olefins-to-gasoline-and-distillate) produces gasoline and distillate in various proportions and, if needed, can be terminated at a point to produce olefin by-products.

In the process, the conversion of methanol to hydrocarbon derivatives and water is virtually complete and essentially stoichiometric in the MTG process. The reaction is exothermic with the reaction heat managed by splitting the conversion in two parts. In the first part, methanol is converted to an equilibrium mixture of methanol, dimethyl ether, and water. In the second part, the equilibrium mixture is mixed with recycle gas and passed over a shape-selective catalyst to form hydrocarbon derivatives and water. Most of the hydrocarbon product boils in the gasoline boiling range. The low-sulfur, low-benzene gasoline product from the process is a premium-quality clean gasoline and can be blended with refinery gasoline directly or sold separately.

See also: Methanol, Methanol – Production, Methanol - Reactions, Methanol-to-Olefins Process, Synthesis Gas.

Methanol-to-Olefins Process

In the UOP methanol-to-olefins (MTO) process, methanol is converted over a zeolite catalyst to give high yields of olefins with some ethylene and low-boiling low-density saturated hydrocarbon derivatives. Generally, catalyst and process variables that increase methanol conversion decrease olefins yield. In the methanol-to-olefins process,

typical conversions exceed 99.9%. The coked catalyst is continuously withdrawn from the reactor and burned in a regenerator.

The UOP/HYDRO MTO process was jointly developed by UOP and Norsk Hydro for the selective production of ethylene and propylene from methanol. The process combines well-proven fluid catalytic cracker (FCC) and naphtha cracker technologies with a proprietary new catalyst from UOP. The catalyst used in the process is based on a silico-alumino-phosphate, SAPO-34.

The MTO process converts methanol to ethylene and propylene at nearly 80% carbon selectivity in a fluidized bed reactor. The MTO reaction is exothermic. Carbon or coke accumulates on the catalyst and must be removed to maintain catalyst activity. The coke is removed by combustion with air in a catalyst regenerator system. Other co-products include small amounts of C_1 - C_4 paraffins, hydrogen, carbon monoxide, and carbon dioxide, as well as ppm levels of heavier oxygenates that are removed to ensure that the product olefins meet polymer-grade specifications.

The methanol-to-olefins process is part of a two-step process, which converts natural gas or coal to methanol followed by the conversion of methanol to low-boiling olefins.

The methanol-to-olefins process provides an alternative to naphtha cracking for the production of ethylene and propylene, and the corresponding polyolefins (GTP – gas to polyolefins) from methanol that can be produced in large quantities from natural gas or other sources such as biomass. The process is flexible with respect to the ethylene/propylene ratio, and the increased future propene demand can be met without an excessive co-production of ethylene.

See also: Methanol, Methanol – Production, Methanol – Reactions, Methanol-to-Gasoline Process, Synthesis Gas.

Methanol-to-Olefins-to-Gasoline Process

The methanol-to-olefins-to-gasoline-and-distillate process (MOGD process, now called the EMOGAS – ExxonMobil Olefins to Gasoline Process) is advanced technology for low-boiling olefins polymerization to gasoline.

In the process, low-molecular-weight olefins produce oligomers in the gasoline boiling range using a zeolite catalyst. Other distillate products are also produced. Gasoline/distillate product ratios can vary, depending on process conditions, from 0.2 to >100.

The direct conversion of natural gas (methane) to liquid fuels involves conversion of methane to the desired liquid fuels while bypassing the synthesis gas step. Direct upgrading routes which have been extensively studied include direct partial oxidation to oxygenates, oxidative coupling to higher-molecular-weight hydrocarbon derivatives, and pyrolysis to higher-molecular-weight products.

In the process, low-boiling olefins are converted to a final gasoline and diesel product. Gasoline and diesel selectivity is greater than 95% of the low-boiling olefin feedstock, and gasoline/diesel product ratios have been produced ranging 0.12 to >100. Because of the catalyst shape selectivity, most products are methyl branched iso-olefins. In the C_5 to C_{10} range, branched iso-olefins have good octane rating. In the C_{10} to C_{20} range, after hydrogenation, iso-paraffins have good diesel fuel properties.

Methyl Alcohol

Methyl alcohol (also known as methanol and wood alcohol) is a chemical with a methyl group linked to a hydroxyl group (CH_3OH , often abbreviated to $MeOH$). It is a low-boiling colorless, flammable liquid, and polar solvent with a distinctive odor similar to the odor of ethyl alcohol.

Methanol is used as a precursor to commodity chemicals, including formaldehyde, methyl tert-butyl ether, methyl benzoate, anisole, peroxyacid derivative, as well as a host to other specialized chemicals.

See also: Methanol, Petrochemicals.

Microalgae

Microalgae are photosynthetic microorganisms that convert sunlight, water, and carbon dioxide to algal biomass.

Microalgae are a diverse group of prokaryotic and eukaryotic photosynthetic microorganisms that grow rapidly due to their simple structure. They can potentially be employed for the production of biofuels in an economically effective and environmentally sustainable manner.

The majority of algae that are intentionally cultivated fall into the category of microalgae (also referred to as phytoplankton, microphytes, or planktonic algae). Macroalgae, commonly known as seaweed, also have many commercial and industrial uses, but due to their size and the specific requirements of the environment in which they need to grow, they do not lend themselves as readily to cultivation.

Microalgae have been investigated for the production of a number of different biofuels including biodiesel, bio-oil, bio-synthesis gas, and bio-hydrogen. The production of these biofuels can be coupled with flue gas carbon dioxide mitigation, wastewater treatment, and the production of high-value chemicals. Microalgae farming can also be carried out with seawater using marine microalgal species as the producers. Developments in microalgal cultivation and downstream processing (e.g., harvesting, drying, and thermochemical processing) are expected to further enhance the cost-effectiveness of the biofuel from microalgae strategy.

Microalgae can provide several different types of renewable biofuels. These include methane produced by anaerobic digestion of the algal biomass, biodiesel derived from microalgal oil, and photobiologically produced biohydrogen. The idea of using microalgae as a source of fuel is not new, but it is now being taken seriously because of the escalating price of crude oil and, more significantly, the emerging concern related to global warming that is associated with burning fossil fuels.

See also: Biomass, Macroalgae.

Microchannel Reactor

A microchannel reactor is a reactor that consists of numerous channels with small diameters of less than a few millimeters, and microchannel process technology is used in a range of applications. These include the large number of chemical and process systems that involve thermal processing, ranging from ethane cracking to fuel processing catalytic processes, such as hydrocracking; chemical reactions and production, for example, steam methane reforming and ethylene oxidation; separations, mixing, and emulsification; catalytic processes; gas processing for operations such as hydrogen production; biological and medical applications; and integrated and multi-phase systems. In terms of small-scale distributed biomass-to-liquids production, microchannel reactors offer particular advantages.

For example, because the structure and dynamics of microchannel reactors improves heat transfer between process fluids and channel walls, the biomass-to-liquids process is intensified. In addition, microchannel reactors also allow the use of more active catalysts than conventional systems, which greatly increases the throughput per unit volume of the reactors. The use of microchannel process technology offers a number of advantages in a range of energy and chemical processing applications. These include: (i) improved heat transfer properties and (ii) higher energy efficiency. Microchannel has thin reaction channels which greatly improves heat and mass transfer. This allows optimal temperature control across the catalyst bed, which maximizes catalyst activity and life.

Mill Residue

Mill residues include bark, coarse residues (chunks and slabs), and fine residues (shavings and sawdust) generated at sawmills that process harvested wood. Primary mill residues tend to be clean, uniform, concentrated, and of low moisture content; most of these materials are already used for products or boiler fuel at the mills.

Mill residue, including chips, sawdust, shavings, and bark, is generated in the process of producing primary wood products. The major primary wood products produced in East Texas include lumber, plywood, veneer, chips, and

posts/poles. Chips as a primary product are produced from pulpwood roundwood; while residue chips are produced from the tops of sawlogs that are used for producing lumber, veneer, or plywood. Sawdust is produced from sawing lumber from sawlogs, and shavings are produced from lumber surfacing. All primary products have bark as mill residue.

The composition varies by mill, but can be as much as 50% solids to 50% water (in the case of paper mill residue, which is classified as lignocellulosic biomass).

Applicable biorefining processes for mill residue are (i) anaerobic digestion, (ii) gasification, (iii) combustion, (iv) fermentation, (v) fiber composite manufacturing, and (vi) thermochemical liquefaction.

Minerals

Minerals are substances formed naturally in the Earth, and they are composed of elements and have a definite chemical composition and structure. Typically, using geology and mineralogy as the guideline, a mineral or mineral species is a solid chemical compound with a fairly well-defined chemical composition and a specific crystal structure that occurs naturally in pure form.

The definition has been further clarified by the International Mineralogical Association to classify a mineral as (i) it must be a naturally occurring substance formed by natural geological processes, (ii) it must be a solid substance in its natural occurrence – a major exception to this rule is native mercury which is still classified as a mineral by the International Mineralogical Association, even though it crystallizes only below -39°C (-38°F), because it was included before the current rules were established, (iii) it must have a well-defined crystallographic structure, and (iv) it must have a fairly well-defined chemical composition.

The exceptions to this definition are the fossil fuels resources that are often classed (in the United States and Canada) among the mineral resources of the country, the state, or the province. However, the United States and Canada are not alone in this expansion of the definition of minerals; many other countries also class the fossil fuel as mineral resources.

Using the geological and mineralogical definition gives rise to more than 3,000 minerals known of which some minerals are rare and precious such as gold and diamond, while others are more ordinary, such as quartz (silica, SiO_2). Approximately 99% of the minerals making up the crust of the Earth are made up of just eight elements. Most of these elements are found combined with other elements as compounds. Minerals are elements or compounds that occur naturally in the crust of the Earth. Rocks are mixtures that are composed of minerals and just as elements are the building blocks of minerals; minerals form the building blocks of rocks.

Minerals are naturally-occurring inorganic solids with well-defined crystalline structures resulting from definite internal structures and composition (Wenk and Bulakh, 2004; Mills et al., 2009; Rafferty, 2011). Minerals are most commonly associated with rocks due to the presence of minerals within the rocks. And these rocks may consist of one type of mineral, or may be an aggregate of two or more different types of minerals that are segregated into separate phases or strata. Silicate minerals comprise approximately 90% of the crust of the Earth. Other important mineral groups include (alphabetically and not in order of abundance): carbonates, halides, native elements, oxides, phosphates sulfates, and sulfides.

Thus, a mineral is formed by a natural process and anthropogenic compounds are excluded. In addition, a mineral is typically abiogenic and does not result from the activity of living organisms. Biogenic substances are chemical compounds produced entirely by biological processes without a geological component and therefore not regarded as minerals. However, if geological processes were involved in the genesis of the compound, then the product can be accepted as a mineral.

Mineral resources have been known and developed throughout historical time, especially ores containing copper (James and Thorpe, 1994). Mineral deposits, including ore bodies and potential ore, can be developed to provide economically valuable commodities (Bain 1987). Therefore, extraction and maximum use must be planned for the benefit of the largest number of people. Such a policy is known as conservation, and it is influenced by many economic and political factors. As costs increase, people tend to use less; they retain materials for more essential uses, thus practicing conservation.

For convenience, raw materials are classified as fuels (see above), metals (including ferrous metals, nonferrous metals, light metals, as well as precious metals), and industrial minerals or nonmetallic elements and have a variety of uses. It is because of these various uses that metals find their way into the environment. The increased demand for a particular metal, coupled with the necessity to utilize lower grade ores, has a significant effect upon the amount of ore that must be mined and processed to produce a unit of a product. Typically, in many industries for every unit of the product, a leaner ore will produce more units of byproducts, some of which can be used and some of which cannot because of the tendency for the by-products to be unusable thereby requiring discharge to the land and/or water systems and the accompanying environmental consequences.

A number of minerals other than those used to produce metals are also important sources of industrial and domestic products. For example, clays, which occur as suspended and sedimentary matter in water and as secondary minerals in soil, are also used for clarifying oils, as catalysts in crude oil processing, as fillers and coatings for paper, and in the manufacture of firebrick, pottery, sewer pipe, and floor tile.

Fluorine compounds are widely used in industry; for example, fluorspar (CaF_2) is used in large quantities as a flux in steel manufacture. Freon-12 (difluorodichloromethane, CF_2Cl_2) is widely used as a refrigeration and air-conditioning fluid and is considered to be a major stratospheric pollutant. Sodium fluoride is used for water fluoridation.

Mica is a complex aluminum silicate mineral which is transparent, tough, flexible, and elastic. Better grades of mica are cut into sheets and used in electronic apparatus, capacitors, generators, transformers, and motors. Finely divided mica is widely used in roofing, paint, welding rods, and many other applications. Phosphorus, along with nitrogen and potassium, is one of the major fertilizer elements. Many soils are deficient in phosphate. The non-fertilizer applications include supplementation of animal feeds, synthesis of detergent builders, and preparation of chemicals such as pesticides and medicines.

Sulfur can exist in many forms which undergo a complicated cycle (Figure 2.4). Sulfur may be expelled from volcanoes as sulfur dioxide or as hydrogen sulfide, which is oxidized to sulfur dioxide and sulfates in the atmosphere. Highly insoluble metal sulfides are oxidized upon exposure to atmospheric oxygen to relatively soluble metal sulfates.

In the ground and in water, sulfate (SO_4^{2-}) is converted to organic sulfur by plants and bacteria. Bacteria mediate transitions among sulfates, elemental sulfur, organic sulfur, and hydrogen sulfide. Sulfur may either escape to the atmosphere (usually as the oxides) and reappear in the form of sulfurous and sulfuric acids in rainfall (acid rain) or be retained as metal sulfides. In fact, the four most important sources of sulfur are (in decreasing order): deposits of elemental sulfur, hydrogen sulfide recovered from sour natural gas, organic sulfur recovered from crude oil, and pyrite (FeS_2).

The development of large machines for handling huge tonnages of rock and the use of refined explosives have improved mining methods, as illustrated in many coal mining operations and in the mining of oil sand. Open-pit and strip mines are larger and more efficient than ever before, and lower grades of ore are being recovered. It is common for a mine to produce 50,000 tons (45,000 metric tons) of ore a day, and some yield more than 100,000 tons (90,000 metric tons).

Improved methods of transportation, concentration, and smelting permit less costly handling of large tonnages and improve recoveries. Newer smelting methods are cleaner, have as good or better recovery records, and may prove to be less expensive to operate. And the environmental aspects of mining many of these minerals need attention. Even the simplest mining procedure such as the recovery of gravel for asphalt highways can have important environmental effects.

The increased use and popularity of mineral resources are due, no doubt, to the relative ease of accessibility which has, in many cases, remained relatively unchanged over the centuries. There are exceptions to the ready availability (crude oil is an example) because of various physical and political reasons, although the prognosis for a continuing crude oil industry remains optimistic through cooperation and planning.

The relatively simple means by which many mineral resources can be utilized has also been a major factor in determining their popularity. And many of the commodities produced from mineral resources:

Ore $\rightarrow$ mineral $\rightarrow$ commodity

The ease with which mineral resources (such as the fossil fuels) were available to the world did, indeed, play a major role in their increased use. The conversion of these natural products to usable products and, in some cases,

to valuable chemicals served to increase their popularity, if coal, crude oil, and natural gas can be used as examples. More specific examples are the coal chemicals industry of the 19th century and the petrochemical industry of the 20th century.

There are projections that the era of fossil fuels (gas, crude oil, and coal) will be almost over when cumulative production of the fossil resources reaches 85% of their initial total reserves. Should the same apply to mineral resources in general, then there may be some cause for concern, perhaps alarming and the issue is worthy of some attention. And a major issue is, naturally, the scarcity of the fossil fuel resources that are used as sources of energy as a means of producing valuable products from a variety of non-fossil fuel resources. For example, the scarcity of crude oil (relative to a few decades ago) is real but it seems more than likely that the remaining reserves of crude oil, coal, and natural gas make it likely that there will be an adequate supply of energy for several decades.

Therefore, technologies to ameliorate the effects of the technologies that are employed in developing the mineral resources must be pursued vigorously. There is a need for on-line analysis of the various product streams (Breen and DeMarco, 1992) to determine the nature of the effluents before they are released to the environment. There is a challenge that must not be ignored, and the effects of, for example, acid rain on soil and water leave no doubt related to the need to control its causes. Indeed, recognition of the need to address these issues is the driving force behind recent energy strategies as well as a variety of research and development.

Miscanthus

Miscanthus (also called silvergrass or silver grass) is a hardy perennial grass that produces a crop of bamboo-like cane up to 15 feet tall. *Miscanthus* is high in lignin and lignocellulose fiber and uses the C4 pathway. It can be grown in a cool climate and on many types of arable land. *Miscanthus* does not require a big input of fertilizers due to its capability to recycle large amounts of nutrients. *Miscanthus* has a similar calorific value per unit weight as wood and therefore could possibly be used in the same power plant or those designed for agricultural residues.

Miscanthus can (theoretically) give an annual harvest of up to 12 tons per acre of dry matter excluding the first couple of years. Like other bioenergy crops, the harvested stems of *miscanthus* may be used as fuel for production of heat and electric power, or for conversion to other useful products such as ethanol. *Miscanthus* is high in lignin and lignocellulose fiber and uses the C4 pathway. It can be grown in a cool climate and on many types of arable land. *Miscanthus* does not require a large input of fertilizers due to its capability to recycle large amounts of nutrients. Once established, the crop can be harvested annually for at least 15 years. By the third year, harvestable yields are between 10 to 13 tonnes (1 tonne = 1,000 kilograms = 2,204.6 lbs) per hectare (1 hectare = 2.47 acres).

Miscanthus is usually planted in April, reaches 1-2 meters in height by late August, starts drying by late July, and is harvested in winter. However, after the first year, the grass is not harvested and the yield of the second year can reach maximum 10 t/ha of dry matter. Planting can be carried out using semi-automatic potato planters for plants, bespoke planters, or manure spreaders for crushed rhizomes (the least favored option). Harvesting can be carried out using a number of different machines such as a mower conditioner or forage harvester to cut the grass, balers to bale the product, and transport with conventional transportation. *Miscanthus* also can be harvested every year with a sugar cane harvester.

Miscanthus is well equipped for high productivity under relatively cool temperatures and may require substantial amounts of water for maximal growth (its growth could therefore also have valuable environmental benefits by acting as absorbing disposal areas for wastewater and some industrial effluents). Furthermore, *Miscanthus* seems to grow well in most soil conditions (bar thin droughty soils) but appears to thrive within areas which are currently best-suited to maize production. The advantages of *Miscanthus* as an energy crop are that it multiplies very rapidly, has a high yield which is relatively dry, and can be harvested annually (from its second season onwards) compared with every 2 to 4 years for short rotation coppice. Further advantages are that *Miscanthus* can be grown and harvested with existing farm machinery, it requires little or no pesticide/fertilizer input after establishment, and the harvest can use the same infrastructure for storage and transport as short rotation coppice. Finally, *Miscanthus* has a

similar calorific value per unit weight as wood and therefore could possibly be used in the same power plant or those designed for agricultural residues.

See also: Short Rotation Coppice.

Miscibility

An equilibrium condition, achieved after mixing two or more fluids, which is characterized by the absence of interfaces between the fluids and involves (i) first-contact miscibility: miscibility in the usual sense, whereby two fluids can be mixed in all proportions without any interfaces forming; an example is at room temperature and pressure, ethyl alcohol and water are first-contact miscible. (ii) multiple-contact miscibility (dynamic miscibility): miscibility that is developed by repeated enrichment of one fluid phase with components from a second fluid phase with which it comes into contact, and (iii) minimum miscibility pressure: the minimum pressure above which two fluids become miscible at a given temperature, or can become miscible, by dynamic processes.

See also: Incompatibility, Stability and Instability.

Mixalco Process

The MixAlco process is an alternative biochemical route for the production of mixed alcohols. In the process, biomass feedstock is mixed with water and pretreated with hydrated lime $[\text{Ca}(\text{OH})_2]$ followed by fermentation using acid-forming microbes which form carboxylic acids. This is followed by addition of calcium carbonate (CaCO_3) which neutralizes the solution and forms dilute carboxylate salts. The salts are then dried and sent to a heated reactor where they are converted to ketones (e.g., acetone), releasing calcium carbonate. Finally, the ketones are hydrogenated to mixed alcohols, predominately propanol, butanol, and pentanol.

The fermentation stage is relatively slow (140-day solids retention time and 14-day liquid retention time) which requires a large reactor volume. To keep costs low, the fermentation stage is envisioned as a covered and lined in-ground lagoon or landfill with recirculating hydrated lime solution. Hydrogen needs to be added at a rate of approximately 0.17 pounds per gallon of alcohol (or 2.6% of final weight). In a full-scale system, mixed alcohol production is estimated to be approximately 60 gallons per dry ton of post-sorted feedstock.

See also: Alcohols, Butanol, Ethanol, Methanol, Propanol.

Mixing

Mixing (sometimes referred to as agitation or blending) is a unit operation widely used in various processes and is an operation in which a uniform combination of two or more components is formed. In addition to blending components together, mixing operations may bring about other desirable changes in the materials being mixed, such as (i) mechanical working, (ii) promotion of heat transfer, and (iii) facilitating chemical or biological reactions such as in fermentation. The components in a mixing operation may be liquids, pastes, dry solids, or gases. The degree of uniformity attainable in a mixing operation varies, depending on the nature of the components. In the case of low-viscosity miscible liquids or highly soluble solids in liquids, a high degree of uniformity is attainable. Less intimate mixing is likely to occur in the case of viscous liquids, pastes, and dry solids. Combining immiscible materials together usually requires specialized equipment. Efficient utilization of energy is another criterion of mixing. This is more easily attainable in the case of low-viscosity liquids as compared with pastes and dry solids.

The various types of mixers in common use are (i) the paddle mixer, (ii) the turbine mixer, and (iii) the propeller mixer. A paddle mixer or mixer consists of a flat blade attached to a rotating shaft, which is usually located centrally in the mixing vessel. The speed of rotation is relatively low, in the range 20 to 150 rpm. The blade promotes rotational and radial flow but little vertical flow. It is usually necessary to fit baffles to the mixing vessel. Two or four blades may be fitted to the shaft. A turbine mixer has four or more blades attached to the same shaft,

which is usually located centrally in the mixing vessel. The blades are smaller than paddles and rotate at higher speeds, in the range 30 to 500 rpm. Simple vertical blades promote rotational and radial flow. Some vertical flow develops when the radial currents are deflected from the vessel walls. A propeller mixer consists of a relatively small impeller, similar in design to a marine propeller, which rotates at high speed, up to several thousand rpm. It develops strong longitudinal and rotational flow patterns. If mounted on a vertical shaft and located centrally in the mixing vessel, baffling is essential. Alternatively, the shaft may be located off center in the vessel and/or at an angle to the vertical.

When mixing highly viscous and paste-like materials, as might be the case in many biomass-to-products processes, it is not possible to create currents which will travel to all parts of the mixing vessel, as happens when mixing low-viscosity liquids. Consequently, there must be direct contact between the mixing elements and the material being mixed. The mixing elements must travel to all parts of the mixing vessel, or the material must be brought to the mixing elements. Mixers for such viscous materials generally need to be more robust, have a smaller working capacity, and have a higher power consumption than those used for liquid mixing. The speed of rotation of the mixing elements is relatively low and the mixing times long compared to those involved in mixing liquids.

Mobile Bed Scrubber

The mobile bed scrubber was designed to clean various gas streams (including coal gas and flue gas) and consisted of thousands of ping-pong-ball-sized hollow hard plastic spheres that were enclosed in cages made from stainless steel rods. Above the mobile bed was a single level of sprays that distributed the scrubbing slurry over the bed. Above the spray header was a mist eliminator. The base of the absorber consisted of a series of pyramidal hoppers, and the discharge from each hopper was the suction to an absorber recycle pump.

The hot gas inlet was between the hopper and the bottom of the mobile bed. To maintain the balls in suspension, gas velocity in the absorber was critical. If the gas velocity was too high, the mobile packing pressed against the top of the cage, causing the scrubbing slurry to accumulate on top of the packing until there was enough head to break through. A gas velocity that was too low caused a similar situation on the bottom of the cage.

Abrasion of the mobile packing was a significant problem. The original, blow-molded hard plastic spheres had a seam which was a weak point, and was subject to wear from the fly ash in the slurry and from rubbing against other spheres. Eventually, the abrasion was sufficient for the spheres to separate at the seam. The half-spheres dropped through the cage rods and into the slurry, where their sharp edges cut the lining of the piping and pumps. UOP then developed a soft plastic sphere the same size as the original spheres. As these balls heated up to the adiabatic saturation temperature of the scrubber, the pores in the spheres would expand letting some of the air contained in the sphere out. This was not a problem until the system was shut down and the spheres cooled to the ambient temperature. No longer maintaining a spherical shape because the air inside the sphere had escaped, they would collapse and drop through the cage rods and get into the scrubbing slurry.

These soft plastic spheres would be found all over the plant site! Some were able to work their way through the mist eliminator blades and then exit the chimney. Others would enter the blowdown and be found floating on the thickener or in ponds.

See also: Gas Cleaning.

Mobil-M Process

The Mobil M process was developed by Mobil Oil Corporation for the purpose of converting methanol directly into high-octane gasoline.

In this process, methanol is first dehydrated to yield dimethyl ether, followed by further dehydration to yield a series of hydrocarbon products:

The distribution of hydrocarbon products is controlled by the zeolite catalyst (a crystalline aluminosilicate with pores, or cavities – the size and geometry of the zeolite pores that control product distribution). Molecules with critical dimensions larger than the pore size cannot be made in the process. Both fixed-bed and fluidized-bed reactors have been employed in developing the Mobil M process.

The crude methanol is vaporized and fed to the first converter stage at approximately 300°C (570°F) and 300 psi where it is catalytically converted to an equilibrium mixture of dimethyl ether, methanol, and water by the reaction:

The first stage product is then combined with a recycle stream and led to the second-stage converter. The inlet temperature is approximately 345°C (650°F), and the outlet temperature is approximately 400°C (750°F). The second-stage converter, filled with catalyst, produces gasoline constituents. The raw product is fractionated, the light ends alkylated, the naphtha recovered from the conversion steps is hydrotreated, and the products blended to produce a gasoline with a 92 research octane-clear (RON) rating.

In the methanol-to-gasoline process, methanol is passed in the vapor phase upward through a catalyst bed at 415°C (775°F) and at 25 psi whereupon the methanol is converted to hydrocarbon derivatives and water. The catalyst is removed from the products at the top of the reactor, and overhead product then condensed and separated from the water; small quantities of coke may also be produced. Some degree of catalyst regeneration is necessary from time to time.

A key characteristic of the M-Gasoline Process is the ability of the catalysts to selectively produce high-octane gasoline constituents. This selectivity is greater than that obtained from classical Fischer-Tropsch-type catalysts. To illustrate, the gasoline selectivity using Mobil catalysts is stated to be as high as 85%, whereas that from Fischer-Tropsch is of the order of 40 to 50%.

See also: Methanol-to-Gasoline.

Moisture in Biomass

Moisture content is the most important characteristic affecting the quality of biomass fuel for thermal processes like combustion, gasification, and pyrolysis. Materials with lower moisture content cost less to transport and can reduce the size of handling, processing, and energy conversion equipment needed for biomass power because a smaller volume of feedstock would be required to meet the fuel requirements for a plant. On the other hand, high moisture content is desirable for a microbial fermentation process, where a liquid water medium is essential.

Moisture content can be measured on a wet or a dry basis. The wet basis method, in which the moisture content is expressed as a percentage of the total weight, is usually used in engineering calculations. In forest product calculations, the dry basis method is used, in which the moisture content is expressed as a percentage of the dry weight of the wood.

The moisture content of freshly harvested forest and crop residue typically varies from 40% to 60% by weight, and can be higher, especially if the residue is exposed to precipitation. The moisture content of crop residue, such as cereal straws, can be reduced to 15% or less by open air solar drying. By contrast, wood residue typically ranges from 18% to 25% MC or more after air-drying for approximately one year, depending on climate, storage conditions, and bulk characteristics. Bark often has lower moisture content than wood. Moisture content can be influenced by weather. Under drought conditions, the moisture content of standing live trees can drop below 20%, adding to the threat of wildfires.

In combustion processes, high moisture content can lead to incomplete combustion, low thermal efficiency, low flame temperatures, excessive emissions, and the formation of tars that could cause slagging problems. Maximum thermal efficiency is achieved at zero moisture content, referred to as *oven-dry* or *bone-dry*, but complete drying is often too costly or impractical. Woody and herbaceous biomass with moisture content in the range of 10% to 20% is considered optimal for conventional combustion systems. Low moisture content is especially important for most pyrolytic gasification processes, where variations in the moisture content of the feedstock cause large variations in the quality of the gas product. Drying costs must be weighed against the advantages of handling drier feedstock and incremental improvements in the conversion process. Some fluid-bed combustors, however, are designed to operate with variable moisture content of the feedstock up to 50%. Many large-scale combustion plants operate well with little apparent concern for the effects of moisture content in the biomass feedstock on the combustion process. Pre-treatment involving size reduction and air drying, and/or blending with dry fuel may be adequate and cost-effective for such operations.

Biomass feedstocks with high moisture content have higher transportation costs because a large proportion of the weight being shipped is water. Because of the negative impact of moisture content on combustion processes and increases in delivered feedstock costs, a good rule is to attempt to minimize the moisture content of the feedstock. This can be done by using a blend of feedstocks, including lower moisture content mill residue such as sawdust to offset higher moisture content forest biomass. Alternatively, it is possible to reduce moisture content through passive or active drying. For ethanol feedstock, the increased delivered costs of biomass with higher moisture content probably outweigh the costs of increased process water requirements, but this needs to be examined on a site-specific basis.

Molten Bath Gasifiers

Unlike combustion processes, gasification is an oxygen-starved process that converts solid fuels (biomass, coal, etc.) into gaseous fuels (Hydrogen and Carbon Monoxide). Gasification is uniquely capable of producing not only heat and power, but also can be used with downstream catalysts to convert the synthesis gas to liquid fuels and chemicals (diesel, ethanol, methanol); and, to hydrogen gas for fuel cell applications.

A number of different carbonaceous feedstocks can be used in gasification process, and, furthermore, the production of synthesis gas enables a number of downstream applications to be integrated with the gasification plant to produce a wide array of products.

Molten bath gasifiers (molten salt gasifiers) use a molten salt as a means of gasifying the carbonaceous feedstocks and may be applicable to biomass gasification.

In the CO₂ Acceptor process, the added medium, namely calcined limestone or dolomite, not only provides the heat for gasification, but also improves the quality of the synthesis gas by virtue of its chemical activity. In molten bath gasifiers, the added media is selected mainly for its chemical functions, while the heat requirements are provided autothermally by introduction of oxygen or air directly into the gasifier. Molten iron is frequently advocated as a suitable medium due to the affinity of iron for sulfur:

Although the prime purpose of the added medium is to provide a sulfur-free fuel or synthesis gas, it also serves ancillary functions. It acts as a dispersing medium for the coal; it acts as a heat sink with high heat transfer rates for distributing the heat of combustion; it also physically retains the ash in the coal. In some cases, the medium may also catalyze the gasification reactions.

The Atomics International (AI) and Kellogg gasifiers are examples of reactors that employ sodium carbonate as the molten medium. The sodium carbonate reacts with the sulfur to form compounds that catalyze the partial oxidation of the coal. The sulfur in the molten salt is removed as hydrogen sulfide in the regeneration system, and elemental sulfur may be recovered as a by-product.

Another molten bath gasification process is the Rummel-Otto gasifier, one version of which has been proven commercially in sizes up to 250 t/d of coal. The molten medium in this gasifier is slag. Unlike other molten media gasifiers, the intent is not to remove pollutants from the product gases. Instead, the slag acts more as a heat shield and as a reservoir for oxygen. Iron oxide in the slag accepts oxygen followed by gasification of the carbon by partial oxidation:

The slag further acts as a promoter of the gasification reactions.

The Rummel-Otto gasifier consists of three zones. In the top zone, the product gases are cooled by direct water quench, the middle zone is an entrained flow combustion/gasification zone of the Texaco and Koppers-Totzek type, while the bottom zone is the slag bath. Dried and pulverized coal is entrained in a recycle gas and injected along with steam and oxygen into the gasifier.

The injection nozzles are oriented tangentially above the slag bath, and the entering feed imparts a slow vortex motion to the slag. The turbulence induced in the slag bath by the injected feed enhances mass and heat transfer between the two phases. Lime may be added as a fluxing agent to decrease the viscosity of the slag.

The steam rate is low but sufficient to moderate the flame temperature to approximately 1,650°C (3,000°F). The reactor vessel in the combustion/gasification zone is both refractory lined and water jacketed. Additional heat shielding is provided by the slag bath.

The gases leaving the gasification zone have high carbon monoxide concentrations as is typical for the high oxygen-to-steam feed ratio and high reaction temperature. On entering the quench zone, they react further with water to increase the H_2/CO ratio to approximately about 1. However, approximately 75% of the total water entering the gasifier remains undecomposed, leaving a gas containing more than 40% moisture by volume. The water quench serves to cool the gases to 980°C (1,800°F) before they enter the cyclones where unreacted char is separated and reinjected into the gasifier. The cold gas efficiency for this plant is approximately 80%.

Molten Salts

A molten salt is a (solid phase) salt which is solid at standard temperature and pressure (STP) but enters the liquid phases at elevated temperature. A salt that is typically liquid even at standard temperature and pressure is usually called a room temperature ionic liquid, although technically, molten salts are a class of ionic liquids.

In most molten salt energy storage systems, the molten salt is maintained as a liquid throughout the energy storage process. In this form of use, molten salts are typically made up of 60% w/w sodium nitrate and 40% w/w potassium nitrate, and the salts melt at approximately 220°C (400°F). Molten salts are often used with concentrating solar power (CSP) plants to store thermal energy for electricity generation.

Molten salt batteries are a class of primary and secondary electric batteries that use molten salts as the electrolyte and offer both a higher energy density through the careful selection of reactant pairs as well as a higher power density by means of a high-conductivity molten salt electrolyte. The batteries are used in services where high energy density and high power density are required, and these features make rechargeable molten salt batteries a promising technology for powering electric vehicles.

Municipal By-Products

The term municipal by-products refers to biomass by-products produced by the urban population and comprise two types: solid municipal by-products, and gas/liquid municipal by-products produced in cities and villages.

Solid municipal biofuels comprise by-products produced by the residential, commercial, industrial, public and tertiary sectors that are collected by local authorities for disposal in a central location, where they are generally incinerated (combusted directly) to produce heat and/or power. Hospital waste is also included in this category. Gas/liquid municipal biofuels refers to biofuels derived principally from the anaerobic fermentation (biogas) of solid and liquid municipal wastes which may be land-fill gas or sewage sludge gas. In fact, many countries have reached a critical stage in the management of our two major municipal by-products such as (i) municipal solid waste (MSW), and (ii) biosolids.

Municipal solid waste consists of a variety of components, including paper and cardboard products, yard wastes, as well as metals, plastic, glass, wood, and food waste. The majority of municipal solid waste but is placed in landfills, but recycling and agricultural uses of municipal solid waste are becoming preferable to landfilling. Many of the components of municipal solid waste (paper, yard waste, food wastes, wood products) are biodegradable under the appropriate conditions and may have potential to be used to improve agricultural and nonagricultural land. Because of limitations associated with odors, pathogens, and undesirable chemical and physical properties, new and unstable organic municipal by-products cannot be added directly to the soil. However, composting of biosolids and selected components of municipal solid waste is an effective waste management process.

Composting is a self-heating microbiological process in which the decomposition of organic materials is accelerated by the growth and enzymatic activity of mixed populations of bacteria and fungi. Composting reduces the weight and volume of the byproduct while abating odors, destroying pathogens, and converting nutrients to forms that biosolids and selected components of municipal solid waste have value as biofertilizers and soil conditioners. However, these materials have relatively low nutrient contents and may need to be enriched with inorganic fertilizers to meet plant growth requirements. Municipal by-products add organic matter to soils, thus maintaining and enhancing soil health and productivity.

Standards have been developed, based on concentrations of trace elements and toxic organics, to regulate land application of biosolids. Currently, the majority of wastewater biosolids are applied to land. Similar regulations are needed for land application of the components of municipal solid waste. The fate and subsequent bioavailability of nutrients, metals, and synthetic organic residues during and after composting of municipal solid waste components will have to be determined. Composted biosolids and municipal solid waste may have potential uses in the horticulture industry as growth media and for biocontrol of soilborne plant diseases. Compost quality and maturity criteria need to be developed to enhance the horticultural uses of municipal by-products.

See also: Municipal Solid Waste, Waste.

Municipal Solid Waste

Municipal solid waste (MSW) consists of a variety of items ranging from organic food scraps to discarded furniture and appliances.

Municipal solid waste is a waste type that includes predominantly household waste (domestic waste) with sometimes the addition of commercial wastes collected by a municipality within a given area. They are in either solid or semisolid form and generally exclude industrial hazardous waste. The term residual waste relates to waste left from household sources containing materials that have not been separated out or sent for reprocessing.

Municipal solid waste is a source of energy probably with as much potential as wood. Non-organic constituents such as metals and glasses must be removed, and may be sold for their recycle value to compensate for the cost of the separation step at least partly. The remaining refuse contains a high proportion of cellulosic material (paper) and other components not readily amenable to biochemical conversion. The characteristics of municipal solid waste can vary significantly with the time of the year, which further detracts from its suitability for biochemical conversion. There are also variations in the constituents, many of which are classed as hazardous (Table M-3).

Table M-3 Examples of toxic constituents in municipal solid waste.

Name*	Formula/symbol	Concern
Non-Metals		
Arsenic	As	Carcinogen and mutagen
Selenium	Se	Long-term toxin
Metals		
Barium	Ba	Long-term circulatory system effects
Cadmium	Cd	Toxic – a carcinogen
Chromium	Cr	Hexavalent compounds are carcinogens and corrosive
Copper	Cu	Toxic by ingestion or inhalation of dust and fumes
Lead	Pb	Toxic by ingestion or inhalation of dust and fumes
Mercury	Hg	Highly toxic by skin absorption and inhalation of vapor
Nickel	Ni	Long-term central nervous system disorders
Silver	Ag	Toxic metal; long-term effects
Organic compounds		
Benzene	C_6H_6	Carcinogen; highly toxic; flammable
Ethyl benzene	$C_6H_5CH_2CH_3$	Toxic by ingestion, inhalation, and skin
Toluene	$C_6H_5CH_3$	Flammable dangerous fire risk. Toxic
Halogenated compounds		
Chlorobenzene	C_6H_5Cl	Moderate fire risk; toxic by inhalation and ingestion
Chloroethylene	CH_2CHCl	Extremely toxic and hazardous ~ all avenues
Dichloromethane	CH_2Cl_2	Carcinogen and narcotic
Tetrachloroethane	$CHCl_2CHCl_2$	Possible carcinogen

*Listed alphabetically within each category.

Wood and yard and tree trimmings are the two sources within this residue stream that are potentially recoverable for energy use. The wood component includes discarded furniture, pallets, containers, packaging materials, lumber scraps (other than new construction and demolition), and wood residuals from manufacturing.

Thermal processes are consequently of interest. Direct combustion for district heating is an obvious application practiced in some countries, while gasification is another possibility. Of particular interest is a scheme for mixing coal, municipal solid waste, and dewatered sewage sludge to produce briquettes suitable for gasification. Apart from supplementing the coal energy, the waste material renders the coals non-caking. Appropriation of these waste materials for energy is not competitive with other uses, and in fact reduces their disposal problem. An additional advantage over other biomass resources is that collection or “harvesting” procedures are both established and financed.

In principal, biomass resources can be converted using any one of a variety of conversion processes. However, depending on their composition and other properties discussed above, some processes can be expected to be more effective than others in recovering energy from a specific resource.

The process/biomass combinations offer a high potential, and in cases where more than one process is suitable, the end product will be an important consideration in selecting among conversion routes. Liquid products are more

versatile than gas and heat. Methanol is not as well suited as ethanol for blending with gasoline to form gasohol, but may prove to be an acceptable stand-alone fuel.

There are six general categories of municipal solid waste which are (i) biodegradable waste such as food and kitchen waste, green waste, paper – which can also be recycled, (ii) recyclable material such as paper, glass, bottles, cans, metals, and certain plastics, (iii) inert waste such as construction and demolition waste, dirt, rocks, and debris, (iv) composite waste which includes waste clothing and waste plastics such as toys, (v) domestic hazardous waste (also called household hazardous waste), and (vi) toxic waste such as discarded medication, paint, chemical, light bulb, fluorescent tube, spray cans, fertilizer and pesticide containers, batteries, and shoe polish.

There is also electronic waste which is a waste consisting of any broken or unwanted electrical or electronic appliance. While there is no generally accepted definition of electronic waste, in most cases, electronic waste consists of electronic products that were used for data processing, telecommunications, or entertainment in private households and businesses that are now considered obsolete, broken, irreparable, or of no further use due to planned obsolescence. Despite its common classification as a waste, disposable electronics are a considerable category of secondary resource due to their significant suitability for direct reuse (for example, many fully functional computers and components are discarded during upgrades), refurbishing, and material recycling of its constituents.

See also: Biomass, Waste.

Municipal Solid Waste – Energy From

The recovery of energy from municipal solid waste (MSW) in its simplest manner has existed for centuries. The burning, or incineration, of wastes such as wood waste and miscellaneous household products, was first used to produce warmth.

In addition, to incineration (which produced a given amount of energy – Table M-4) gaseous fuels can also be obtained by anaerobic digestion in conjunction with landfill gas recovery.

Table M-4 Comparison of heating values of various waste-derived fuels.

Fuel Source	Btu/lb
Yard Wastes	3,000
Municipal solid waste	6,000
Combustible paper products	8,500
Textiles and plastics	8,000
Bituminous coal (average)	11,300
Anthracite coal (average)	12,000
Spent tires	13,000-15,000
Crude oil (average)	17,000
Natural gas (425 ft ³)	13,500

One method of recovering usable energy from MSW is gasification in which the waste material is gasified under high pressure by the injection of air and steam with concurrent gas/solid flow. After separation of the non-combustible waste, water or oil is added to the combustible municipal solid waste to form a pumpable slurry. The resulting slurry is then pumped under pressure to the gasifier. In the gasifier, the slurry is reacted with air at high temperatures. The resultant gaseous product is then sent to a scrubbing system to remove any pollutants and impurities.

Anaerobic digestion of solid waste is a process similar to that used for biogas production. Anaerobic bacteria, in the absence of oxygen, are used to break down the organic matter of the waste. Frequently, the municipal solid waste is mixed with sewage sludge from the treatment plant to enhance the efficiency of the digestion and the production of a mixture of methane and carbon dioxide gases – the typical ratio of the gas mixture is 70% methane and 30% carbon dioxide, and the gas mixture has a heating value on the order of 650 to 750 BTU/ft³.

Pyrolysis of municipal solid waste has also been used to generate a gaseous fuel. However, pyrolyzing a cellulose-based waste atmospheric pressure will generate a liquid fuel.

A typical pyrolytic reaction for the cellulose component of municipal solid waste may be written as:

The formula $\text{C}_6\text{H}_8\text{O}$ represents a family of liquid products, but the actual composition of $\text{C}_6\text{H}_8\text{O}$ is dependent on the feedstock composition and the reaction temperature.

When the pyrolysis temperature is higher than 350°C (660°F), small quantities of polyethylene chips can be added to the cellulose feedstock. Operating temperatures ranging from 100 to 400°C (210 to 750°F) decrease the amount of gaseous product and increase the formation of the liquid product.

In addition to the liquid fuel or oil, pyrolysis generates a medium-BTU gas stream that, after purification, can be recycled as a supplemental fuel within the plant. Process water and char are also generated. The process water may have to be treated before discharge, or can be used in the plant as heat exchanger water. All of the pyrolysis products have the potential of being useful fuels or intermediates for producing other valuable products for use in the petrochemical industry.

Although there are a number of MSW-derived fuel systems in full operation and/or being started up throughout the world, there are still developmental issues in regard to process design and engineering, pollution control and monitoring, equipment design and selection, and application-related information. The cost-to-benefit analysis along with the environmental impact analysis must be carefully conducted for any chosen process and site.

Municipal Waste

Municipal waste (sometimes, depending upon the composition referred to as municipal solid waste, MSW), commonly known as trash or garbage in the United States and rubbish in the United Kingdom is a waste type consisting of everyday items that are discarded by the public. Although the waste may originate from a number of sources that has nothing to do with a municipality, the traditional role of municipalities in collecting and managing these kinds of waste have produced the particular term municipal waste, which often includes wastes of similar character from shops, market and offices, open areas, and treatment plant sites (Table M-5)

Table M-5 Sources of municipal waste

Source	Types
Residential	Food waste
	Garbage
	Ash
	Hazardous waste
Commercial	Food waste
	Garbage
	Ash
	Demolition waste
	Construction waste
	Treatment plant sludge
	Hazardous waste

In order to develop frameworks within which effective waste management strategies can be planned, it is essential to know not only the amounts of waste generated and their sources, but also the type of materials in each waste stream, their properties, potential toxicity, and the hazards they pose to human health and the environment. The lack of reliable time series on solid waste streams and rapid changes in the composition of waste streams are a serious impediment to setting priorities in solid waste management in many developed as well as developing countries.

Municipal wastes in developing countries have a higher proportion of organic matter and ash, higher moisture content, and lower paper content, although refuse from the wealthier suburbs is similar in composition to West European wastes. Organic matter and ash may account for between 60 and 85% of all wastes in low income settlements.

However, despite the large amounts of waste produced by individuals in the wealthy industrialized nations, municipal wastes account for a small proportion of total wastes generated.

Changes in the composition of municipal wastes in developed countries have undoubtedly taken place both at the community and national levels, but data are still relatively sparse. In general, the proportion of ash and grit has decreased, while the proportion of plastics has been growing.

An important component of domestic wastes in industrialized countries is the “bulky” or “consumer durables” wastes, e.g., cars, refrigerators, and washing machines. The number of items discarded each year is growing as rapid changes in technology and production of new models reduces what is perceived to be their useful life.

See Biomass, Municipal Solid Waste, Waste.

Muon

The muon (formerly referred to as a mu meson) is an elementary particle that is similar to the electron with an electric charge of $-1 e$ and a spin of $\frac{1}{2}$ but with a much greater mass. The muon is not known to have any substructure – that is, it is not thought to be composed of any simpler particles. The muon is an unstable subatomic particle with a lifetime on the order of 2.2 microseconds – a microsecond is a unit of time equal to one millionth (0.000001 or 10^{-6}) of a second.

As with the decay of the non-elementary neutron (with a lifetime on the order of 15 minutes), muon decay is slow (by subatomic standards) because the decay is mediated only by the weak interaction because the mass difference between the muon and the set of its decay products is small. Muon decay almost always produces at least three particles, which must include an electron of the same charge as the muon and two types of neutrinos.

Like all elementary particles, the muon has a corresponding antiparticle of opposite charge ($+1 e$) but equal mass and spin – the antimuon (also called a *positive muon*). Muons are denoted by μ^- and antimuons by μ^+ . Muons were formerly called *mu mesons*, but are not classified as mesons.

Mustard Seed

Mustard (*Brassica juncea*) is the common name for multiple species in the *Brassica* genus. The species of which most people are aware is yellow mustard, referred to as white mustard in Europe, and is grown primarily for condiment mustard seed. As a result, it does not have as high oil content as the other commonly known Indian mustard referred interchangeably in commerce as brown or oriental mustard. *Juncea* varieties are grown for edible leaves or greens or for condiment mustard, and have been and are increasingly grown as an oilseed crop.

The crops commonly called rapeseed and canola in commerce are also in the *Brassica* genus, and are *Brassica napus* species. As a result, they are closely related to *juncea*. Because canola is not a botanical term, but one used to describe compositional qualities, the term is often used with *juncea* when discussing cultivars that have been developed for the oilseed market. Canola varieties of *napus* and canola-type *juncea* have similar compositional characteristics but different crop or agronomic qualities. In theory, oils from both species have the same acid profiles (high in mono-saturate derivatives and low in saturate derivatives) and oil characteristics (lower pour and melting point and better cold flow properties) and similar meal properties (a protein content on the order of 35 to 40% w/w) with low

glucosinolate levels – glucosinolate derivatives are the natural components of many pungent plants such as mustard, cabbage, and horseradish).

Glucosinolate structure

The key differences between *napus* and canola-type *junceae* lie in the agronomic characteristics. Both are an annual, cool season crop, but *junceae* tolerates high temperatures and drought better than *napus*, and thus is better suited for the warmer, drier climates of the Upper Plains of the United States.

Although pure mustard oil is banned for use as a vegetable oil in many countries, it is often applied topically and used as a massage oil, skin serum, and hair treatment. However, in the current context, mustard oil contains approximately 20 to 28% w/w oleic acid, 10 to 12% w/w linoleic acid, 9.0 to 9.5% w/w linolenic acid, and 30 to 40% w/w erucic acid, which leaves an option for the oil as a starting material for the production of alternative fuels.

See also: Biodiesel, Fatty Acids.

Naft

Naft is the pre-Christian era (Greek) term for naphtha, which was the main constituent of Greek fire, which was one of the most effective thermal devices, although it was extremely dangerous for the users. A combustible liquid, it could be shot from siphons or catapults, and it bursts into flames on impact. First developed by the Byzantines in the 7th century, it was later used by the Turks during the Crusades, and was probably first used in Western Europe in the 12th century. Early experiments by the Byzantines in the 6th century used a mixture of sulfur and oil, which would have been terrifying if not destructive. Various versions seem to have existed, and the recipes were frequently kept secret and the exact composition is still speculative.

The incendiary liquids of the ancient and medieval periods have their modern equivalents. World War I saw the development of the flamethrower, a modern version of the Byzantine siphons for discharging Greek fire, which used gas under pressure to squirt a mixture of inflammable oil and petrol, ignited by a burning taper. The twentieth century and the latter half saw the development and use of napalm, an incendiary liquid formed in part from naphtha (naft).

Naphtha

Naphtha is a generic term applied to refined, partly refined, or unrefined mixture of flammable liquid hydrocarbons, the majority of which distills below 240°C (464°F); the volatile fraction of crude oil which is used as a solvent or as a precursor to gasoline. Naphtha normally refers to, i.e., a distillation product from crude oil or boiling in a certain range and containing certain hydrocarbons, a broad term encompassing any volatile, flammable liquid hydrocarbon mixture. In fact, the generic name naphtha describes a range of different products that satisfy the boiling range (and other physical properties) that can be produced from alternate energy sources) that can be used in different applications and produced by various processes (Table N-1).

Table N-1 Naphtha production by various crude oil refining processes.

Process	Primary product	Secondary process	Secondary product
Atmospheric distillation	naphtha		low-boiling naphtha
			high-boiling naphtha
	gas oil	catalytic cracking	naphtha
	gas oil	hydrocracking	naphtha
Vacuum distillation	gas oil	catalytic cracking	naphtha
		hydrocracking	naphtha
	residuum	coking	naphtha
		hydrocracking	naphtha

Naphtha is used primarily as a gasoline blend stock as well as for producing a high octane gasoline component (via the catalytic reforming process). It is also used in the petrochemical industry for producing olefins in steam crackers and in the chemical industry for solvent (cleaning) applications.

The origin of the word naphtha is unclear, having been borrowed by the ancient Greeks from the Old Persian words nafta, naft, and neft, which were used to describe bubbling oil. Naphtha may also have been derived from the

name of the Vedic Hindu and Avestic god Apam Napat, a form of Agni, or fire god. In older usage, naft or neft simply meant crude oil and the words still find use in some languages.

Naphtha is obtained from crude oil as one of the intermediate products from distillation. It is a liquid intermediate between the gases in the crude oil and the higher-boiling kerosene.

The molecular weight range for naphtha constituents is 100 to 215 g/mol; the specific gravity range is 0.75 to 0.85 g/cm³; the boiling point range is to 165 to 225°C (320 to 430°F); the vapor pressure is <5 mm Hg (<5 torr). Naphtha is insoluble in water; colorless (kerosene odor) or red-brown (aromatic odor) liquid; incompatible with strong oxidizers.

Generally, less dense (low-boiling) naphtha will have a higher paraffin content and is often referred to as *paraffinic naphtha*. The main application for this type of naphtha is as a feedstock in the petrochemical production of olefins. When used as feedstock in petrochemical steam crackers, naphtha is heated in the presence of water vapor, and the absence of oxygen and the primary products of the cracking process are olefins (ethylene, propylene, and butadiene) and aromatics (benzene, toluene).

The more dense (high-boiling) naphtha is usually richer in naphthenes and aromatics, and therefore, this type of naphtha can also be used in the petrochemical industry but is more often used as a feedstock for refinery catalytic reformers where it converts the lower octane naphtha to a higher octane (*reformate*).

In terms of renewable energy sources, the hydrothermal liquefaction process (HTL process) or direct liquefaction is a promising technology to treat waste streams from various sources and produce valuable bio-products such as biocrude oil. A major problem with commercializing the hydrothermal liquefaction processes for biomass conversion is that it remains uneconomical when compared to the costs of diesel or gasoline production. High transportation costs of large quantities of biomass increase production costs, and poor conversion efficiency coupled with a lack of understanding complex reaction mechanisms inhibits growth of the process commercially.

In the hydrothermal liquefaction process, biomass is reacted in liquid water at elevated temperature and pressure. The phase equilibria in the hydrothermal liquefaction process are complicated due to the presence of water, supercritical carbon dioxide, alcohols as well as the so-called biocrude. The biocrude is a mixture with a wide molecular weight distribution and consists of various kinds of molecules. Biocrude oil contains 10 to 13% w/w oxygen and is upgraded by catalytic hydrodeoxygenation in a central facility. Preliminary process studies on the conversion of various biomass types into liquid fuels have indicated that hydrothermal liquefaction is more attractive than pyrolysis or gasification.

The biomass is typically fed to the process as a 25% w/w slurry in water, and is treated at temperatures of 300 to 430°C (570 to 805°F) at varying pressures in the presence of liquid water for 5 to 20 minutes to yield a mixture of gas (mainly carbon dioxide) and synthetic crude oil (sometimes referred to as biocrude). Subsequent processing is necessary of the synthetic crude oil to usable fuel (Goudriaan and Peferoen, 1990).

Biomass, such as wood, with a lower energy density is converted to biocrude with higher energy density, organic compounds including mainly alcohols and acids, gases mainly including carbon dioxide. Water is also a by-product. In the products, carbon dioxide, which is the main constituent of the gas product, can be used to represent all gas produced, and methanol and ethanol represent organic compounds. The weight fraction of each component is assigned on the basis of the data of the vacuum flash of biocrude.

See also: Refining.

Naphthalene and Polynuclear Aromatic Hydrocarbons

Naphthalene is a two-ring condensed aromatic hydrocarbon that is produced during the carbonization of carbonaceous materials that must be removed from the gas stream to avoid plugging of lines and valves in subsequent gas usages. It may be scrubbed from the gas with hydrocarbon (usually wash oil) and then separated by distillation. Another removal method is to reabsorb it in tar. Naphthalene may be extracted in the crystalline form as pure material.

Naphthalene is probably the most abundant component in high-temperature coal tar. The primary fractionation of the crude tar concentrates the naphthalene into oils which, in the case of coke-oven tar, contain the majority (75

to 90% w/w) of the total naphthalene. After separation, naphthalene can be oxidized to produce phthalic anhydride which is used in the manufacture of alkyd resins and glyptal resins and plasticizers for polyvinyl chloride.

Naphthalene and its homologs are less acutely toxic than benzene but are more prevalent for a longer period during oil spills. The toxicity of different crude oils and refined oils depends on not only the total concentration of hydrocarbons but also the hydrocarbon composition in the water-soluble fraction (WSF) of crude oil, water solubility, concentrations of individual components, and toxicity of the components. The water-soluble fractions prepared from different oils will vary in these parameters. The water-soluble fractions (WSF) of refined oils (for example, No. 2 fuel oil and Bunker C oil) are more toxic than the water-soluble fraction of crude oil to several species of fish (killifish and salmon). Compounds with either more rings or methyl substitutions are more toxic than less substituted compounds, but tend to be less water soluble and thus less plentiful in the water-soluble fraction.

Among the polynuclear aromatic hydrocarbons, the toxicity is a function of its di- and tri-aromatic hydrocarbon content. Like the single aromatic ring variations, including benzene, toluene, and the xylenes, all are relatively volatile compounds with varying degrees of water solubility.

There are indications that pure naphthalene (a constituent of moth balls that are, by definition, toxic to moths) and alkyl naphthalene derivatives are from three-to-ten times more toxic to test animals than are benzene and alkylbenzene derivatives. In addition, and because of the low water solubility of tricyclic and polycyclic (polynuclear) aromatic hydrocarbons (that is, those aromatic hydrocarbon derivatives that are higher-boiling – higher molecular weight – than naphthalene), these compounds are generally present at low concentrations in the water-soluble fraction of oil. Therefore, the results of this study and others conclude that the soluble aromatics of crude oil (such as benzene, toluene, ethylbenzene, xylenes, and naphthalenes) produce the majority of its toxic effects in the environment.

Once the acutely toxic lower-boiling compounds have left the aquatic environment through volatilization or degradation, the main concern is chronic effects from higher-boiling and more alkylated polynuclear aromatic hydrocarbons.

Bird species with water habitats are the species most commonly affected by oil spills and releases. Oil itself breaks down the protective waxes and oils in the feathers and fur of birds and animals and disrupts the fine strand structure of the feathers resulting in a loss of heat retention and buoyancy and possible hypothermia and death. Oiled birds often ingest crude oil while attempting to remove the crude oil from their feathers. The effects of ingested crude oil include anemia, pneumonia, kidney, and liver damage, decreased growth, altered blood chemistry, and decreased egg production and viability. Ingestion of the oil can also kill animals by interfering with their ability to digest food. Chicks may be exposed to crude oil by ingesting food regurgitated by impacted adults.

The dynamics of the oil-in-water dispersion (OWD) are complex and have relevance related to potential toxicity or hazard. In comparing the toxicities to marine animals of oil-in-water dispersions prepared from different oils, not only the amount of oil added but also the concentrations of oil in the aqueous phase and the composition and dispersion-forming characteristics of the parent oil must be taken into consideration. In comparing the potential impacts of spills of different oils on the marine biotic community, the amount of oil per unit water volume required to cause mortality is of greater importance than any other aspect of the crude oil behavior.

Several compounds in crude oil products are carcinogenic. The larger and higher- molecular-weight aromatic structures (with four to five aromatic rings), which are the more persistent in the environment, have the potential for chronic toxicological effects. Since these compounds are non-volatile and are relatively insoluble in water, their main routes of exposure are through ingestion and epidermal contact. Some of the compounds in this classification are considered possible human carcinogens; these include benzo(a)pyrene, benzo(e)pyrene, benzo(a)anthracene, benzo(b)fluorene, benzo(j)fluorene, benzo(k)fluorene, benzo(ghi)perylene, chrysene, dibenzo(ah)anthracene, and pyrene.

Mixtures of polynuclear aromatic hydrocarbons are often carcinogenic and possibly phototoxic. One way to approach site-specific risk assessments would be to collect the complex mixture of polynuclear aromatic hydrocarbons and other lipophilic contaminants in a semi-permeable membrane device (SPMD, also known as a *fat bag*), then test the mixture for carcinogenicity, toxicity, and phytotoxicity.

The solubility of hydrocarbon components in crude oil products is an important property when assessing toxicity. The water solubility of a substance determines the routes of exposure that are possible. Solubility is approximately

inversely proportional to molecular weight; lower-boiling hydrocarbons are more soluble in water than higher-molecular-weight compounds. Lower-molecular-weight hydrocarbons (C4 to C8, including the aromatic compounds) are relatively soluble, up to approximately 2,000 ppm, while the higher-molecular-weight hydrocarbon derivatives are nearly insoluble. Usually, the most soluble components are also the most toxic.

Finally, the toxicity of crude oil may be affected by factors such as weathering time or the addition of oil dispersants. *Weathered* crude oil and *fresh* crude oil may have different toxicities, depending on oil type and weathering time.

See also: Alkanes, Cycloparaffin Hydrocarbon derivatives.

Naphthenes

Naphthenes (cycloalkane derivatives, cycloparaffin derivatives) are types of alkane derivatives which have one or more rings of carbon atoms in the chemical structure. Cycloalkanes with a single ring are named analogously to their normal alkane counterpart of the same carbon count: for example cyclopropane, cyclobutane, cyclopentane, and cyclohexane.

Naphthenes are similar to alkanes in their general physical properties, but they have higher boiling points, melting points, and densities than alkanes. Cycloalkanes exhibit a similar low reactivity as alkanes, due to relatively unreactive carbon-carbon and carbon-hydrogen; however, the ring strain can cause induce increased reactivity in cycloalkanes.

The boiling point and densities of naphthenes are higher than those of alkane derivatives having the same number of carbon atoms. Naphthenes commonly present in crude oil are rings with five or six carbon atoms. Examples of naphthenes are (Figure N-1):

Figure N-1 Examples of naphthene derivatives.

These rings usually have alkyl substituents attached to them (Figure N-1). Multi-ring naphthenes are present in the higher-boiling fraction of crude oil.

See also: Alkanes, Cycloparaffin Hydrocarbons, Refining.

Natural Gas

Natural gas (also incorrectly, in this context, called marsh gas, swamp gas, and landfill gas) is the flammable gaseous mixture that usually occurs with crude oil reservoirs and which provides approximately 24% of the world's energy sources, and the use of natural gas as an energy source is expected to increase over the next several decades.

Natural gas is a mixture of hydrocarbon and small quantities of non-hydrocarbon derivatives that exists either in the gaseous phase or is in solution in crude oil in natural underground reservoirs, and which is gaseous at atmospheric conditions of pressure and temperature (Table N-2).

Table N-2 Range of composition of natural gas.

Constituents	Formula	% v/v
Methane	CH ₄	>85
Ethane	C ₂ H ₆	3-8
Propane	C ₃ H ₈	1-2
Butane	C ₄ H ₁₀	<1
Pentane	C ₅ H ₁₂	<1
Carbon dioxide	CO ₂	1-2
Hydrogen Sulfide	H ₂ S	<1
Nitrogen	N ₂	1-5
Helium	He	<0.5

Natural gas is generally considered to be of biogenic origin and is the result of the decay of animal remains and plant remains (organic debris) that has occurred over millions of years. Over time, the mud and soil that covered the organic debris changed to rock and trapped the debris beneath the newly-formed rock sediments. Pressure and, to some extent, heat (as yet undefined) changed some of the organic material into coal, some into crude oil, and some into natural gas. Whether or not the debris formed coal, crude oil, or gas depended upon the nature of the debris and the localized conditions under which the changes occurred.

Natural gas is found in reservoirs beneath the surface of the earth and is often associated with crude oil, although gas that is not associated with crude oil is also known. Production companies search for evidence of these reservoirs by using up-to-date technology that helps to determine the location of the gas and drill wells in the earth where it is likely to be found. Once brought from underground, the natural gas is refined to remove impurities like water, other gases, sand, and other compounds. Some hydrocarbon derivatives are removed and sold separately, including propane and butane. Other impurities are also removed, like hydrogen sulfide (the refining of which can produce sulfur, which is then also sold separately). After refining, the clean natural gas is transmitted through a network of pipelines that deliver natural gas to its point of use. Two new, and possibly large sources of methane that can be expected to extend the availability of natural gas, are methane hydrates (also called gas hydrates) and coal bed methane. Their production technologies have only recently been developed, and these sources are now becoming economically competitive.

Methane-rich gases are also produced by the anaerobic decay of non-fossil organic material and are generally referred to as biogas. Sources of biogas include (i) swamps, which produce swamp gas, (ii) marshes, which produce marsh gas, (iii) landfills, which produce landfill gas, (iv) as well as sewage sludge and manure, which produce gas by way of anaerobic digesters, and (v) livestock methane, which is produced by enteric fermentation in cattle.

Natural gas is a vital component of the supply of energy of the world, and it is one of the cleanest, safest, and most useful of all energy sources. However, it needs to be understood that the word gas has a variety of different uses, and meanings. Fuel for automobiles is also called gas (being a shortened version of gasoline), but that is a totally different fuel. The gas used in a barbecue grill is actually propane (C₃H₈), which, while associated with and commonly found in natural gas and crude oil, is not really natural gas.

Natural gas is the flammable gaseous mixture that occurs alone or with crude oil in reservoirs and is predominantly methane (CH₄) and some of the higher-molecular-weight higher paraffins (C_nH_{2n+2}) generally containing up to five carbon atoms (Table N-2). Non-flammable non-hydrocarbon components such as carbon dioxide (CO₂), hydrogen sulfide (H₂S), nitrogen (N₂), and helium (He) are often also present in natural gas. Carbon dioxide, nitrogen, and helium detract slightly from the heating value of natural gas. However, they are valuable and in certain natural gases where their concentrations are relatively high, they may be extracted commercially. In its purest form, as delivered to the consumer, natural gas is almost pure methane and the remaining hydrocarbon derivatives and non-hydrocarbon derivatives have been removed through refining.

Natural gas is colorless, shapeless, and odorless in its pure form. Quite uninteresting – except that natural gas is combustible, and when burned, it gives off a great deal of energy. Unlike other fossil fuels, however, natural gas is clean burning and emits lower levels of potentially harmful by-products into the air. It is the environmental aspect of gas use that is currently elevating the use of natural gas as an energy source of high importance.

There are several general definitions that have been applied to natural gas science and technology. For example, lean gas is gas in which methane is the major constituent. On the other hand, wet gas contains considerable amounts of the higher-molecular-weight hydrocarbon derivatives. To further define the terms dry and wet in quantitative measures, the term dry natural gas indicates that there is less than 0.1 gallon (1 gallon, US, = 264.2 m³) of gasoline vapor (higher-molecular-weight paraffins) per 1,000 ft³ (1 ft³ = 0.028 m³). The term wet natural gas indicates that there are such paraffins present in the gas, in fact more than 0.1 gal/1,000 ft³. Natural gas is considered dry when it is almost pure methane, having had most of the other commonly associated hydrocarbon derivatives removed. When other hydrocarbon derivatives are present, the natural gas is wet.

Sour gas contains hydrogen sulfide, whereas sweet gas contains little, if any, hydrogen sulfide. Residue gas is natural gas from which the higher-molecular-weight hydrocarbon derivatives have been extracted, and casing head gas is derived from crude oil but is separated at the separation facility at the well-head.

Natural gas is considered as an environmentally friendly clean fuel, offering important environmental benefits when compared to other fossil fuels. The superior environmental qualities over coal or crude oil are that emissions of sulfur dioxide are negligible or that the level of nitrous oxide and carbon dioxide emissions is lower. This helps to reduce problems of acid rain, ozone layer, or greenhouse gases. Natural gas is also a very safe source of energy when transported, stored, and used.

Neem Oil

Neem oil is a vegetable oil pressed from the fruits and seeds of neem (*Azadirachta indica*), an evergreen tree which is endemic to the India and has been introduced to many other areas in the tropics. It is perhaps the most important of the commercially available products of neem for organic farming and medicines.

Neem oil is generally light to dark brown, bitter, and has a rather strong odor that is said to combine the odors of peanut and garlic. It comprises mainly triglycerides and large amounts of triterpenoid compounds, which are responsible for the bitter taste. It is hydrophobic in nature, and in order to emulsify it in water for application purposes, it must be formulated with appropriate surfactants.

Neem oil also contains steroids (campesterol, beta-sitosterol, stigmasterol) and a variety of triterpenoids of which azadirachtin is the most well-known.

While it has not yet been produced on a commercial scale, neem oil is being considered for biodiesel. The methyl esters of pongamia, Jatropha, and neem are derived through transesterification process, and these methyl esters (biodiesels) can be directly used in diesel engines without any engine modifications.

See also: Biodiesel, Transesterification, Vegetable Oil.

Neutralization Number

Neutralization is a process for reducing the acidity or alkalinity of a waste stream by mixing acids and bases to produce a neutral solution – also known as pH adjustment. The neutralization number is a measure of the acid or alkaline content of new oils and an indicator of the degree of oxidation degradation of used oils and, therefore, a number that indicates the degree of acidity or alkalinity of a substance determined by finding the amount of alkali or acid.

More specifically, thus, the neutralization number is the weight, in milligrams, of potassium hydroxide needed to neutralize the acid in 1 g of oil, which is an indication of the acidity of an oil.

See also: Acidity and Alkalinity, Acid Number.

Neutron

The neutron is a subatomic particle (symbol n or n^0 , which has a neutral (not positive or negative) charge and a mass slightly greater than that of a proton. Along with protons, neutrons constitute the nuclei of atoms. Since protons and neutrons behave similarly within the nucleus, and each has a mass of approximately one atomic mass unit, they are both referred to as nucleons.

The chemical properties of an atom are mostly determined by the configuration of electrons that orbit the nucleus of the atom nucleus. In addition, the electron configuration is determined by the charge of the nucleus, which is determined by the number of protons, or atomic number. The number of neutrons is the neutron number, and the neutrons do not affect the electron configuration, but the sum of atomic and neutron numbers is the mass of the nucleus and the isotopes of a chemical element differ only in neutron number. Neutrons are produced copiously in nuclear fission and in nuclear fusion.

See also: Electron, Neutron Moderator, Nuclear Fission, Nuclear Fusion, Proton.

Neutron Moderator

A neutron moderator is a medium that reduces the speed of fast neutrons without (in theory) without capturing any of the neutrons, thereby leaving them as thermal neutrons with only minimal thermal (kinetic) energy. These thermal neutrons are more susceptible than fast neutrons to propagate a nuclear chain reaction of uranium-235 (^{235}U) or another fissile isotope by colliding with the atomic nuclear.

Thus, the function of the moderator is to slow down the fast neutrons and the atoms of the moderator material need to have a size close to neutrons. These materials should have low neutron absorption cross section and can also act as a coolant requiring high thermal conductivity and heat capacity to absorb the heat. The primary function of a coolant is to transfer heat generated at the nuclear reactor core.

Light water is the most commonly used moderator, although the term is slightly ambiguous, usually meaning natural fresh water but typically refers to deuterium-depleted water. Solid graphite and heavy water (D_2O , $^2\text{H}_2\text{O}$) are the main alternatives for neutron moderators. Beryllium has also been used as a neutron moderator, and hydrocarbon derivatives have been suggested as another possibility.

The main benefit of using a moderator in a nuclear explosive is that the amount of fissile material needed to reach the critical stage may be greatly reduced. Slowing of fast neutrons will increase the cross section of the neutron absorption, thereby reducing the critical mass. However, there is a side effect – as the chain reaction progresses, the moderator will be heated, thus losing its ability to cool the neutrons. Another effect of moderation is that the time between subsequent neutron generations is increased, slowing down the reaction. This makes the containment of the explosion a problem; the inertia that is used to confine implosion-type bombs will not be able to confine the reaction. The end result may be a lower reaction climax rather than a prominent explosion.

See also: Nuclear Energy, Nuclear Fission, Nuclear Reactor.

Nitrogen Cycle

The nitrogen cycle is complex, involving the conversion of atmospheric nitrogen (N_2) to ammonia (NH_3) and nitrate (NO_3) derivatives through different mechanisms. While nitrogen in the soil can increase agricultural yields, excess reactive nitrogen is responsible for many environmental problems, including acidification, smog formation, eutrophication/hypoxia (a condition in which the body or a region of the body is deprived of adequate oxygen supply), and global warming potential in the form of nitrous oxide (N_2O). Also, nutrient runoff from fertilized soybean fields provokes eutrophication which is an accumulation of nutrients in water that prompts algal blooms. Organisms in the affected aquatic environment will die and decay, creating a high oxygen demand. Extreme cases of eutrophication create hypoxia and drive oxygen levels so low that the ecosystem is no longer capable of supporting life.

See also: Biogeochemical Cycles.

Nitrogen Oxides

Nitrogen oxides (NO_x) are produced during combustion; precursors to acid deposition (acid rain). NO_x is a generic term for mono-nitrogen oxides (NO and NO_2). These oxides are produced during combustion. At ambient temperatures, the oxygen and nitrogen gases in air will not react with each other.

In the presence of excess oxygen (O_2), nitric oxide (NO) will be converted to nitrogen dioxide (NO_2).

When NO_x and volatile organic compounds (VOCs) react in the presence of sunlight, they form photochemical *smog*, a significant form of air pollution, especially in the summer.

Mono-nitrogen oxides eventually form nitric acid when dissolved in atmospheric moisture, forming a component of acid rain:

Nitric oxide will oxidize to form nitrogen dioxide that again reacts with water, ultimately forming nitric acid:

Mono-nitrogen oxides are also involved in production of ozone in the troposphere.

Nitrogen Oxides Control

Nitrogen oxides are produced in the combustion of fuels; nitrogen oxides (NOX) control can be approached in two ways: by adjusting combustion conditions to minimize nitrogen oxides production, or by cleaning the nitrogen oxides that are produced from the stack gases. Combustor conditions can be designed for low NOX production, and gas cleaning systems can also be added in the future if the need arises for further control of nitrogen oxides.

See also: Gas Cleaning.

Noise Control

Preparation plants for the production of feedstocks invariably contain various types of active machinery, in addition to large throughput tonnage of free-falling solids, and have long been recognized as presenting a serious noise problem. Most of the noise control measures may be classified broadly into measures that (1) suppress noise formation or (2) provide noise containment. Examples of the former include the installation of mufflers on air pumps and of rubber screen cloths and resilient screen decks and chute liners. Noise containment requires erection of barriers, either walls or curtains.

Non-Hydrocarbon Components

Crude oil which contains only hydrocarbon derivatives is, in fact, an extremely complex mixture. The phenomenal increase in the number of possible isomers for the higher hydrocarbon derivatives makes it difficult, if not impossible in most cases, to isolate individual members of any one series having more than, say, 12 carbon atoms.

Inclusion of organic compounds of nitrogen, oxygen, and sulfur serves only to present crude oil as an even more complex mixture than was originally conceived. Nevertheless, considerable progress has been made in the isolation and/or identification of the lower- molecular-weight hydrocarbon derivatives, as well as accurate estimations of the overall proportions of the hydrocarbon types present in crude oil. Indeed, it has been established that, as the boiling

point of the crude oil fraction increases, not only the number of the constituents but the molecular complexity of the constituents also increases.

Crude oils contain appreciable amounts of organic non-hydrocarbon constituents, mainly sulfur-, nitrogen-, and oxygen-containing compounds and, in smaller amounts, organometallic compounds in solution and inorganic salts in colloidal suspension. These constituents appear throughout the entire boiling range of the crude oil but tend to concentrate mainly in the higher-boiling fractions and in the non-volatile residues.

Although their concentration in certain fractions may be quite small, their influence is important. For example, the decomposition of inorganic salts suspended in the crude can cause serious breakdowns in refinery operations; the thermal decomposition of deposited inorganic chlorides with evolution of free hydrochloric acid can give rise to serious corrosion problems in the distillation equipment. The presence of organic acid components, such as mercaptans and acids, can also promote metallic corrosion. In catalytic operations, passivation and/or poisoning of the catalyst can be caused by deposition of traces of metals (vanadium and nickel) or by chemisorption of nitrogen-containing compounds on the catalyst, thus necessitating the frequent regeneration of the catalyst or its expensive replacement.

The presence of traces of non-hydrocarbon derivatives may impart objectionable characteristics in finished products, such as discoloration, lack of stability on storage, or a reduction in the effectiveness of organic lead antiknock additives. It is thus obvious that a more extensive knowledge of these compounds and of their characteristics could result in improved refining methods and even in finished products of better quality. The non-hydrocarbon compounds, particularly the porphyrins and related compounds, are also of fundamental interest in the elucidation of the origin and nature of crude oils. Furthermore, knowledge of their surface-active characteristics is of help in understanding problems related to the migration of oil from the source rocks to the actual reservoirs.

Non-Methane Hydrocarbons

Non-methane hydrocarbons (Table N-3) are the organic compounds of carbon and hydrogen that are not straight chain, saturated (no more hydrogen can be added) molecules in which the carbon atoms are joined to each other by single bonds.

Table N-3 Simple non-methane hydrocarbons.

Number of carbon atoms	Alkane	Alkene	Alkyne	Cycloalkane	Alkadiene
2	Ethane	Ethylene	Acetylene		
3	Propane	Propylene	Propyne	Cyclopropane	
4	Butane, iso-Butane	Butene	Butyne	Cyclobutane	Butadiene
5	Pentane, iso-Pentane, Neopentane	Pentene	Pentyne	Cyclopentane	Pentadiene
6	Hexane	Hexene	Hexyne	Cyclohexane Methylcyclopentane Ethylcyclobutane Propylcyclopropane	Hexadiene
7	Heptane	Heptene	Heptyne	Cycloheptane Methylcyclohexane	Heptadiene
8	Octane	Octene	Octyne	Cyclooctane	Octadiene
9	Nonane	Nonene	Nonyne	Cyclononane	Nonadiene
10	Decane	Decene	Decyne	Cyclodecane	Decadiene

Because of differences in molecular structure, the empirical formula remains different between hydrocarbons; in linear, or straight-chain alkanes, alkenes and alkynes, the amount of bonded hydrogen lessens in alkenes, and alkynes due to the self-bonding or catenation of carbon preventing entire saturation of the hydrocarbon by the formation of double or triple bonds.

In simple chemistry, as per valence bond theory, the carbon atom must follow the 4-hydrogen rule which states that the maximum number of atoms available to bond with carbon is equal to the number of electrons that are attracted into the outer shell of carbon. In terms of shells, carbon consists of an incomplete outer shell, which comprises 4 electrons, and thus has 4 electrons available for covalent or dative bonding.

Non-Conventional Fuel Sources

Non-conventional fuel sources are sources of fuels (alternate or synthetic fuels) other than traditional crude oil. Three types of non-conventional oil reserves can be discerned: heavy crude oil, extra heavy crude oil, and tar sand bitumen. Medium heavy crude oil and extra heavy crude oil are mobile at reservoir conditions but are typically immobile at ambient temperature, but the highly viscous tar sand bitumen is immobile at deposit (reservoir) conditions.

Gaseous, liquid, or solid synthetic fuels are obtained by converting a carbonaceous material to another form. The most abundant naturally occurring materials suitable for this purpose are (i) tar sand bitumen, (ii) extra heavy crude oil, (iii) coal, and (iv) oil shale. The conversion of these raw materials to synthetic fuels can replace depleted, unavailable, or costly supplies of natural fuels.

Biomass is another carbonaceous material that can also be converted to synthetic fuels – such as the fermentation of grain to produce alcohol, which is the best-known example. Wood is also an abundant and accessible source of bio-energy, and the procedures for the gasification of cellulosic materials have much in common with the conversion of coal to gas.

Currently, non-conventional oil production is less efficient and some types have a larger environmental impact relative to conventional oil production. Non-conventional types of production include tar sand, extra heavy crude oil, coal, oil shale, and biofuels as well as liquid fuels from natural gas through processes such as the Fischer-Tropsch process. These non-conventional sources of oil may be increasingly relied upon as fuel for transportation as the price of conventional crude oil increases and supplies dwindle.

However, conventional sources of liquid fuels from crude oil are currently preferred because they provide a much higher ratio of extracted energy over energy used in extraction and refining processes. Technology, such as using steam injection in heavy crude oil reservoirs, continues to serve as a means of extracting heavy crude oil, while mining serves as the only commercial production of tar sand bitumen.

See also: Bitumen Coal, Crude Oil.

NO_x

NO_x refers to the oxides of nitrogen that are produced during combustion or nitrogen-containing fuels or, under certain circumstances, when air is used as the source of oxygen. Thermal NO_x refers to NO_x formed through high temperature oxidation of the diatomic nitrogen found in combustion air. The formation rate is primarily a function of temperature and the residence time of nitrogen at that temperature. At high temperatures, usually above 1,600°C (2,900°F), molecular nitrogen (N₂) and oxygen (O₂) in the combustion air disassociate into their atomic states and participate in a series of reactions forming a variety of nitrogen oxides.

In fact, the term NO_x or nitrogen oxides typically refers to any binary compound of oxygen and nitrogen, or to a mixture of such compounds:

- Nitric oxide (NO), nitrogen(II) oxide.
- Nitrogen dioxide (NO₂), nitrogen(IV) oxide.
- Nitrous oxide (N₂O), nitrogen(I) oxide.
- Dinitrogen trioxide (N₂O₃), nitrogen(II, IV) oxide.

Dinitrogen tetroxide (N_2O_4), nitrogen(IV) oxide.

Dinitrogen pentoxide (N_2O_5), nitrogen(V) oxide.

The last three compounds are unstable but may be formed during the combustion process before decomposing to more stable forms of nitrogen oxide.

Mono-nitrogen oxides eventually form nitric acid when dissolved in atmospheric moisture, forming a component of acid rain:

Technologies such as flameless oxidation (FLOX) and staged combustion significantly reduce thermal NOx in industrial processes. Water Injection technology, whereby water is introduced into the combustion chamber, is also becoming an important means of NOx reduction through increased efficiency in the overall combustion process. Alternatively, the water (e.g., 10 to 50%) is emulsified into the fuel oil prior to the injection and combustion. This emulsification can either be made in-line (unstabilized) just before the injection or as a drop-in fuel with chemical additives for long-term emulsion stability (stabilized). Other technologies, such as selective catalytic reduction (SCR) and selective non-catalytic reduction (SNCR), reduce post combustion NOx.

Nuclear Energy

Nuclear energy is energy that can be released from the nucleus of an atom. There are two ways to produce this energy, either by fission or fusion. Fission occurs when the atomic nucleus is split apart. Fusion is the result of combining two or more light nuclei into one heavier nucleus.

Atoms are made up of several parts: protons, neutrons, electrons, and a nucleus. A nucleus is the positively charged center of an atom. Protons are positively charged particles, and neutrons are uncharged particles. Electrons orbit around the nucleus and are negatively charged. Fission can occur in two ways—first, in some very heavy elements, such as rutherfordium, the nucleus of an atom can split apart into smaller pieces spontaneously.

With lighter (lower atomic weight) elements, it is possible to hit the nucleus with a free neutron, which will also cause the nucleus to break apart, and a significant amount of energy is released when the nucleus splits. The energy released takes two forms: light energy and heat energy. Radioactivity is also produced. Atomic bombs let this energy out all at once, creating an explosion. Nuclear reactors let this energy out slowly in a continuous chain reaction to make electricity. After the nucleus splits, new lighter atoms are formed. More free neutrons are thrown off that can split other atoms, continuing to produce nuclear energy.

Nuclear energy can be used for various industrial applications, such as seawater desalination, hydrogen production, district heating or cooling, the extraction of tertiary oil resources, and process heat applications such as cogeneration, coal-to-liquids conversion, and assistance in the synthesis of chemical feedstock. A large demand for nuclear energy for industrial applications is expected to grow rapidly on account of steadily increasing energy consumption, the finite availability of fossil fuels, and the increased sensitivity to the environmental impacts of fossil fuel combustion. With increasing prices for conventional oil, unconventional oil resources are increasingly utilized to meet such growing demand, especially for transport.

Nuclear binding energy is the energy required to split a nucleus of an atom into the component parts. The term nuclear binding energy may also refer to the energy balance in processes in which the nucleus splits into fragments composed of more than one nucleon. If new binding energy is available when light nuclei fuse, or when heavy nuclei split, either of these processes result in releases of the binding energy. This energy, available as *nuclear energy*, can be used to produce electricity (nuclear power) or as a nuclear weapon.

An absorption or release of nuclear energy occurs in nuclear reactions of radioactive decay. Those reactions that absorb energy are called endothermic reactions, and those that release energy are exothermic reactions. Energy is consumed or liberated because of differences in the nuclear binding energy between the incoming and outgoing products of the nuclear transmutation.

Thus, nuclear energy or nuclear power is the use of exothermic nuclear process of nuclear binding energy to generate useful heat and electricity. The term includes nuclear fission, nuclear decay, and nuclear fusion. Presently, the nuclear fission of elements in the actinide series of the Periodic Table of the Elements produce the vast majority of nuclear energy in the direct service of humankind, with nuclear decay processes, primarily in the form of geothermal energy, and radioisotope thermoelectric generators, in niche uses making up the remainder.

Nuclear energy offers a low carbon alternative and has important potential advantages over other sources being considered for future energy. There are no technological impediments to extracting heat and steam from a nuclear power plant. This has been proven for low temperatures (<200°C) with nuclear assisted district heating and desalination with an experience of approximately 750 reactor operation years from around 70 nuclear power plants. Detailed site-specific analyses are essential for determining the best energy option. The development of small- and medium-sized reactors would therefore be better suited for cogeneration and would facilitate non-electric applications of nuclear energy. The possibility of large-scale distribution systems for heat, steam, and electricity supplied from a central nuclear heat source (such as a multiproduct energy center) could attract and serve different kinds of consumers concentrated in industrial parks.

Nuclear energy is energy in the core of an atom which is made up of three particles – protons, neutrons, and electrons. Protons carry a positive electrical charge, and electrons carry a negative electrical charge. Neutrons do not have an electrical charge. The energy is located in the bonds that hold the nucleus together. This nuclear energy can be released when those bonds are broken. The bonds can be broken through nuclear fission, and this energy can be used to produce (generate) electricity.

The main interest in this source of energy is physically based on the so-called energy mega-factor. When comparing the energy released by a chemical reaction, as in the combustion phase of a coal (C) atom or a methane (CH₄) molecule, with a nuclear reaction on a nucleus of uranium (²³⁵U isotope) by a neutron (n), the amount of energy (Q, in electron volts) differs from six orders of magnitude:

In this equation, F1 and F2 are fission fragments.

Thus, in terms of energy release, 1 unit weight of nuclear fuel (UO₂) is energetically equivalent to 128 thousand units (by weight) of wood, or 70 thousand units (by weight) of crude oil, or 80 thousand (by weight) of coal with no emissions of carbon dioxide. However, there are other hazards to the use of nuclear energy that must be addressed as part of the planning process. These include the disposal of spent nuclear fuel as well as the potential for a nuclear meltdown.

Energy from nuclear sources may be the result of nuclear fission, which uses uranium ore or refined uranium-235 (²³⁵U) as its basic energy source. In nuclear fission, atoms are split apart (hence the term fissile material as applied to the source) which releases energy. All nuclear power plants use nuclear fission, and most nuclear power plants use uranium atoms. During nuclear fission, a neutron collides with a uranium atom and splits it, releasing a large amount of energy in the form of heat and radiation. More neutrons are also released when a uranium atom splits. These neutrons continue to collide with other uranium atoms, and the process repeats itself over and over again. This process is called a nuclear chain reaction. This reaction is controlled in nuclear power plant reactors to produce a desired amount of heat.

For this type of energy, the ore must be concentrated into fissionable isotopes through nuclear processing. Eventually, the spent material must be replaced, and the resources of uranium ore may be limited as determined by a specific test (ASTM E901). Hence, the need to explore the potential for generating more of the fissionable isotopes.

However, the use of such materials has become the core of a major controversy which threatens to be, at least for the time being, the death-knell of the nuclear industry.

Nuclear fusion, unlike nuclear fission which involves the use of fissionable material, involves the fusion of hydrogen nuclei. The concept has been suggested as having the potential to provide a clean and virtually unlimited supply of energy. However, it is generally felt that the technology is at the stage where several decades appear to be needed for the performance of believable laboratory-scale experiments which are critical to the development of controlled energy from fusion.

In nuclear fusion, the atoms are combined or fused together to form a larger atom. Fusion is the source of energy in the sun and stars. Developing technology to harness nuclear fusion as a source of energy for heat and electricity generation is the subject of ongoing research, but whether or not it will be a commercially viable technology is not yet clear because of the difficulty in controlling a fusion reaction.

Currently, at nuclear power plants, the heat to make the steam is created through nuclear fission which releases heat. In a nuclear power plant, uranium is the material used in the fission process and the heat from fission is used to create steam to turn a turbine which, in turn, produces electricity. However, nuclear energy can be as hazardous as any fossil fuel in terms of destruction of the environment, and deserves some comment insofar as an appreciation of its use may assist in the general background and aid in putting fossil fuel resources into a more complete context.

Nevertheless, as long as suitable safety regulations are applied, energy from nuclear sources has shown potential to be a significant energy source in the future. The technology is known but has suffered some setbacks. Accidents and dubious claims of the ease with which energy may be derived from nuclear sources have reduced the credibility of the nuclear industry. Nevertheless, the potential still exists for the extraction of energy from nuclear sources.

Hence, the continued use of the so-called conventional fuel resources is derived from the remains of ancient plants and animals. Those same resources which have been instrumental in the phenomenal expansion of the industrialized world. And also, those same resources which can have serious adverse effects on the flora and fauna (including man) of the world.

Nuclear Energy – Environmental Impact

The chief benefit to the environment of nuclear power plants is that they do not emit (give off) harmful gases, such as carbon dioxide and sulfur dioxide. In this way, nuclear power plants differ from conventional (natural gas-fired, crude oil-fired, coal-fired) power plants, which emit these gases primarily because they burn coal, a fossil fuel. If the energy generated by nuclear power plants worldwide were instead generated by burning coal, the amount of additional carbon dioxide released into the atmosphere would be approximately 1,600 million tons. Moreover, burning coal releases toxic heavy metals, including arsenic, cadmium, lead, and mercury.

By not emitting these gases, nuclear energy does not contribute to environmental problems such as air pollution, smog, and the greenhouse effect, which refers to the ability of some gases (such as carbon dioxide) to accumulate in the air, thereby trapping the heat from the Sun which causes an increase in average temperatures around the world – often referred to as global warming which is blamed for the melting of the polar ice, raising sea levels and endangering coastal cities. Furthermore, by not emitting pollutants (such as nitrogen oxides and sulfur oxides), nuclear power plants do not contribute to acid rain. Acid rain is any form of precipitation that is more acidic than normal because the water has absorbed acidic pollutants from the air. Acid rain can harm crops and forests. It can also contribute to the deterioration of buildings and public monuments, which dissolve because of the acid in precipitation.

Nuclear power plants also do not harm surrounding bodies of water. A myth that some people believe is that nuclear plants discharge water into nearby lakes and streams that is either radioactive or extremely hot. This is not true. The water released from a nuclear plant never comes into contact with the radiation. Further, if the water is too hot to be discharged, it is cooled either in a cooling pond or in cooling towers before release.

However, nuclear power plants have a low impact on the environment, especially when compared to hydroelectric dams. While such dams have the benefit of not emitting harmful gases or pollutants, the dams have a major impact on the surrounding environment. By turning rivers into huge lakes, they disrupt vegetation and wildlife. Many dams have displaced (driven out) large numbers of people. Further, the reservoirs behind hydroelectric dams emit their own form of pollution. As the water level of the reservoir falls, the wet ground that surrounds it supports the growth

of vegetation. As the water rises, this vegetation is covered and rots. The rotting vegetation emits methane gas, a pollutant. In addition, hydroelectric dams have an adverse effect on fish because they disrupt breeding and spawning grounds.

Nuclear power plants do not have harmful effects on wildlife. In fact, they often can have beneficial effects. For example, when cooled water is released from the plant, the water often contributes to the formation of wetlands. These wetlands can become nesting grounds and provide habitat for birds, fish, and other animals. Some companies that build and run nuclear plants even develop wildlife preserves and parks in the surrounding area, where plants grow abundantly in the moist soil.

See also: Acid Rain.

Nuclear Fission

An atom is made up of three kinds of particles: neutrons, protons, and electrons. Two of these particles, neutrons and protons, are found in the nucleus, or center, of an atom. A neutron does not have an electrical charge. It is called a neutron because its electrical charge is neutral. A proton has a positive electrical charge. Circling around the nucleus of an atom in layers are electrons, which have a negative electrical charge. To keep the overall electrical charge neutral, an atom has to have the same number of protons and electrons. Positive and negative electrical charges attract each other. The charges bind the particles of an atom together. When an atom is split, some of this energy is released.

When a nucleus undergoes fission, a considerable amount of energy is released. The energy carried by the neutrons represents a small fraction of the total energy released. Most of this energy is carried by the fission products in the form of kinetic energy. Expelled at a velocity of in excess of 8,000 kilometers (5,000 miles) per second, these fission products push their way through the other atoms by knocking against them. During these collisions, they rapidly lose their speed (and thus energy) by heating up the surrounding environment, before stopping in the bulk of the uranium. Their initial energy is finally transformed into heat, and the local temperature in the uranium increases. In a nuclear reactor, this heat is recovered to generate electricity.

By far the most important element for nuclear fission is uranium-235 (^{235}U or U-235), and it is the principal constituent of the fuel rods in a nuclear reactor. In a fission reaction, besides the two fission products, several neutrons (in the case of U-235, typically two to three) are emitted.

For example, in 235 grams of U-235, there are as many as 6×10^{23} atoms (the Avogadro number) and all of these atoms can undergo fission. Thus:

In this fission event, one among billion quadrillion identical ones, the fissionable uranium atom (nucleus) reacts with a neutron, becomes temporarily unstable, and is fragmented very soon thereafter into a nucleus of barium (Ba) and a nucleus of krypton (Kr). Also, the number of protons on the left-hand side of a nuclear equation (in this case, $92 + 0 = 92$) is equal to the number of protons on the right-hand side ($56 + 36 = 92$); the number of neutrons is also equal on both sides of the equation ($235 + 1 = 144 + 89 + 3$). Atoms are not conserved, but nucleons are. This is the difference between a chemical reaction and a nuclear reaction. Also, atoms are conserved in chemical reactions; they are just rearranged to form different molecules. In nuclear reactions, nucleons are rearranged to form different nuclei but they are conserved.

Nuclear fission is an example of a chain reaction in which each one of the three neutrons produced in the first fission event goes on to collide with other U-235 nuclei. This new collision event will in turn produce three additional neutrons; so after two collisions, a total of nine neutrons will be obtained. This increase in neutron inventory (3-9-27-81-243-729-et seq) is similar to the population rise and is an example of exponential growth. Because this exponential growth is accompanied by heat release, an exponential buildup of heat occurs at the same time. There is no way to dissipate or carry away all this heat, so the temperature of the solid material (within which fission occurs) increases; the material melts and then vaporizes. This in turn causes a pressure buildup which ultimately results in an explosion, just like in an overinflated balloon.

Thus, the principle of chain reaction involves bombardment of the uranium-235 nucleus neutrons, upon which fission occurs at a high probability. The neutrons produced in this process can cause more fissions, and, consequently, the process becomes self-sustaining and no external neutron source is needed any longer. If the neutrons produced from a fission induce only one new fission (because of escaping from the system or being captured inside), we say that the chain reaction is of constant intensity. If the neutrons generated from a fission reaction induce more than one fission, then more and more fission reactions will take place in a unit time and the chain reaction will be diverging.

As much as 85% of the energy released in the fission process appears as kinetic energy of the fragments. As the high-speed fragments collide with surrounding matter, they induce random motion of the surrounding atoms and molecules; their kinetic energy is thus converted to heat. This heat is used in turn to produce electricity in a nuclear reactor or is allowed to cause an explosion in an atomic bomb. The fate of the neutrons produced in the fission process is the key to understanding the difference between a controlled nuclear reaction, which takes place inside a nuclear reactor, and an uncontrolled nuclear reaction, which leads to the explosion of an atomic bomb.

The probability that a high energy neutron emitted in a fission reaction can directly cause fission is quite low. In order to build a system in which fast neutrons sustain the chain reaction, very highly enriched uranium is needed. A more easily feasible way is to use materials that slow the neutrons down to such low energies at which the probability of causing a fission is significantly higher. These neutrons slowing down materials are the so-called moderators. With the aid of some adequate moderator, one might as well achieve chain reaction using natural (0.7% U-235 content) uranium.

Typically, at the fission of uranium-235, two to three neutrons are released, but not all of these cause fission. The neutronic state can be characterized by the so-called multiplication factor (k), which is the ratio of the number of neutrons in a neutron generation and the number of neutrons in the preceding generation. The neutron generation is the time that elapses between the birth of a neutron and the birth of neutrons from the subsequent fission which is caused by the given neutron and is on the order of 10^{-9} second (i.e., 1 nanosecond) for pure uranium-235. The number of neutrons present in the reactor must be regulated or controlled since this determines the rate of fission and thus the energy released per second. In order to control the chain reaction, one should use materials which tend to capture neutrons at a high probability. The most widespread neutron absorbers are cadmium (Cd) and boron (B).

The so-called control rods are important tools of control and can be found in every reactor. These are made of neutron-absorbing materials and can be moved between the fuel assemblies. For example, if one wishes to decrease the power of the reactor, it is sufficient to push in a control rod a little further. The control rods are particularly useful for short-term control and stopping the reactor. For long-term regulation, usually boric acid dissolved in the coolant is used.

Nuclear Fusion

The nuclear fusion process is the opposite of the fission process and involves the combination of light (low density, low atomic number) nuclei in order to release excess binding energy, and they form a heavier nucleus. Fusion reactions are responsible for the energy of the sun. They have also been used on earth for uncontrolled release of large quantities of energy in the thermonuclear or hydrogen bombs. However, the enormous potential and the problems associated with controlled use of this essentially nondepletable energy source need side-by-side consideration.

The concept of nuclear fusion occurs when the nuclei of two light atoms are brought closer to each other, they become increasingly destabilized, due to the electric repulsion of their positive charges. Work must be expended to achieve this, and so the energy of the two nuclei increases. If this activation energy is provided to overcome the repulsive forces, fusion of the two nuclei into a stable heavier nucleus will take place and a large amount of energy will be released. The net energy output is potentially larger in the case of fusion than in the case of fission. For example, the fusion of deuterium (shown as H^2) and tritium (shown as H^3) into helium (He) is only one of the possible reactions that could be the basis for the fusion power reactors of the future. Thus:

In this equation, *p* signifies a proton, *n* signifies a neutron, and *Li* is lithium.

Deuterium and tritium are the main ingredients in most fusion reactions. Deuterium is a stable form of hydrogen; it does occur (as trace amounts) in ordinary water. Tritium is a radioactive form of hydrogen that does not occur in nature. In contrast to the situation with fission, where tritium is produced (and thus contributes to radioactivity), here it is consumed. As shown above, it can be obtained from lithium, Li-6, a relatively abundant metal found in mineral ores. A simple calculation, based on the fact that there is one deuterium atom in every 6,500 atoms of hydrogen, shows that in 65,000 pounds of water, there is approximately one pound of deuterium.

The reaction between deuterium (H^2) and tritium (H^3) has the fast reaction rate and requires the lowest temperature of all the fusion reactions, so it is the first choice for a fusion power plant. Adequate sources of deuterium and tritium are thus important, independent of what type of confinement system, magnetic or inertial, is employed.

One gram of deuterium will produce 300 GJ of electricity, and providing for all of the world's present-day energy consumption (equivalent to approximately 3×10^{11} GJ per year) would require approximately 1,000 tons of deuterium a year. The source of deuterium is straightforward because approximately 1 part in 6,700 of water is deuterium, and 1 gallon of water used as a source of fusion fuel could produce as much energy as 300 gallons of gasoline. When all the water in the oceans is considered, this amounts to over 10^{15} tons of deuterium – enough to supply our energy requirements indefinitely. Extracting deuterium from water is straightforward using electrolysis, and the cost of the fuel would be negligible compared to the other costs of making electricity. Since water is an abundant resource on the Earth, and the fact, together with the fact that enormous amounts of energy are released in fusion reactions, makes fusion an essentially nondepletable energy source.

A second series of nuclear reactions can convert hydrogen into helium, and it is now thought that it is the dominant process in stars that are hotter and more massive than the Sun. The reaction sequence is as follows:

In the first stage, a proton reacts with a ${}^{12}\text{C}$ nucleus to form nitrogen ${}^{13}\text{N}$, which is unstable and decays to ${}^{13}\text{C}$. Further stages build up through ${}^{14}\text{N}$ and ${}^{15}\text{O}$ to ${}^{15}\text{N}$, which then reacts with a proton to form ${}^{12}\text{C}$ and ${}^4\text{He}$. At the end of the sequence, the ${}^{12}\text{C}$ has been recycled and can start another chain of reactions, so it acts as a catalyst. Overall, four protons have been replaced with a single helium nucleus, so the energy release is the same as for the proton cycle.

Fusion offers several advantages over fission such as (i) the reserves of fusible isotopes are much larger than those of fissionable isotopes and (ii) the products of fusion reactions are less radioactive than the products of fission reactions. Among the products of the fusion reactions listed above, only tritium and the neutrons are radioactive. In addition, fusion is inherently safe. Insofar as there would be little fusible material at any given time in the reactor, and the likelihood of a runaway reaction would thus be small and perhaps even unlikely.

The basic challenges of fusion are the following: (i) heating of the reacting mixture to a high temperature, to overcome the repulsive forces of positively charged nuclei, (ii) compressing the mixture to a high density so that the probability of collision and, thus, reaction among the nuclei can be high, and (iii) keeping the reacting mixture together long enough for the fusion reaction to produce energy at a rate that is greater than the rate of energy input (as heat and compression).

The first challenge is that of providing a huge amount of energy to the reactants – fusion is a thermonuclear reaction. The second and third challenges are collectively referred to as the confinement problem. It is easily understood that the reacting mixture – called ‘plasma’ at the high temperatures involved – cannot be brought together (or confined) in ordinary vessels. The presence of solid vessels is ruled out because they would carry away the heat necessary to reach the high ignition temperatures. Magnets (magnetic confinement) and lasers (inertial confinement) are used instead.

Nuclear Power

Nuclear power is the power derived from the fission or fusion of atomic species. The primary use of nuclear power is the large-scale generation of base load electricity by the fission (i.e., splitting) of the uranium isotope (^{235}U). At present, there is still public concern related to the use of nuclear power. However, a more careful analysis shows that this form of energy is considerably more desirable than is currently perceived and will likely be one of the main practical solutions for the future production of CO_2 free electricity.

There are several comparisons with fossil fuel plants that show why nuclear power has received so much attention as a source of electricity. The first involves the energy content of the fuel. A nuclear reaction produces on the order of one million times more energy per elementary particle than a fossil fuel chemical reaction. The implication is that much less nuclear fuel is required to produce a given amount of energy.

A second point of comparison is environmental impact. Nuclear power plants produce neither carbon dioxide nor other harmful emissions. This is a major environmental advantage. Another issue is safety. The worst accident in a USA plant occurred at Three Mile Island. This was a financial disaster for the power company but only a negligible amount of radiation was released to the environment. The reason is that Western nuclear power plants are designed with many overlapping layers of safety to provide “defense in depth” culminating with a huge, steel reinforced containment vessel around the reactor to protect the public in the case of a worst accident. The large loss of life and wide environmental damage resulting from the Chernobyl accident occurred because there was no containment vessel around the reactor.

A major issue is the extent of the reserves of nuclear fuels. In the simplest sense, it can be assumed that uranium-235 is the basic fuel and once most of it has been consumed in the reactor, the resulting spent fuel rods are buried in a permanent, non-retrievable repository. In this scenario, there is enough uranium-235 to provide electricity at the present rate for several hundred years. On the other hand, the spent fuel rods contain substantial amounts of plutonium which can be chemically extracted and then used as a new nuclear fuel. In fact, it is possible to use the resulting plutonium in such a way that it actually breeds more plutonium than is being consumed. The use of such “breeder” reactors extends the reserves of nuclear fuels to many thousands of years. Breeders are more expensive than conventional nuclear plants and are not currently used because of the ready availability of low-cost uranium-235. However, in the long term, breeders may be one of the energy sources of choice.

Nuclear waste and how to dispose of it is another important issue. Here too, there are subtleties. One point is that many of the radioactive fission by-products have reasonably short half-lives, on the order of 30 years or less. They need to be stored for approximately one hundred years during which time they self-destruct by radioactive decay into a harmless form, an ideal end result. It is the long-lived, multi-thousand year wastes that receive much public attention and scrutiny. Several possible solutions have received serious consideration. The waste can be dissolved in glass (i.e., vitrification) and permanently stored. The fuel can be chemically reprocessed for re-use in regular or breeder reactors, thereby transforming much of the long-lived waste into useful electricity. Third, there are techniques that, while currently expensive, transmute long-lived, non-fission radioactive waste by-products into harmless elements.

Also, a critical point is that the total volume of nuclear waste is small. The total nuclear “rubbish” resulting from powering Boston for one year would fill up only a small fraction of a pickup truck. The conclusion is that there are a variety of technological solutions to the waste disposal problem.

See als: Nuclear Energy, Nuclear Fission, Nuclear Fusion, Nuclear Power Plant, Nuclear Reactor.

Nuclear Power Plant

A nuclear power plant is a system in which some of the energy released by nuclear fission is used to generate electricity. Every such plant contains four fundamental elements: reactor, coolant system, electrical–power generating unit, and safety system. In the plant, heat is produced during nuclear fission to boil water into steam, which turns the blades of a steam turbine. As the turbine blades turn, they drive generators that make produce electricity.

The source of energy in a nuclear reactor is a fission reaction in which neutrons collide with nuclei of uranium-235 (^{235}U) or plutonium-239 (^{239}Pu) (the fuel), causing them to split apart. The products of a fission reaction include not only energy but also new elements (known as fission products) and free neutrons. A constant and reliable flow of neutrons is insured in the reactor by a moderator, which slows down the speed of neutrons, and by control rods, which limit the number of neutrons available in the reactor and, hence, the rate at which fission can occur. In a nuclear weapon, the fission chain reaction), once triggered, proceeds at an exponentially increasing rate, resulting in an explosion. In a nuclear reactor, the process proceeds at a steady, controlled rate. Most commercial nuclear power plants are incapable of undergoing an explosive nuclear chain reaction, even should their safety systems fail. However, this is not the case with all research reactors (such as some breeder reactors).

Energy produced in the reactor is carried away by means of a coolant such as pressurized water, liquid sodium, or carbon dioxide. The circulating coolant absorbs heat in the reactor; once outside the reactor, it is allowed to boil or the heat it contains is used to boil water in a secondary loop. Steam produced in either of these ways is then piped into the electrical generating unit, where it turns the blades of a turbine. The turbine, in turn, turns a generator that produces electrical energy.

Every nuclear plant is also required to have an elaborate safety system to protect against the most serious potential problem of all, loss of coolant. If such an accident were to occur, the reactor core might melt itself down, possibly breaching the structures which contain it and releasing radioactive materials to the rest of the plant and, perhaps, to the outside environment. To prevent such an accident, the pipes carrying the coolant to and from the reactor are required to be very thick and strong. In addition, backup supplies of the coolant must be available to replace losses in case of a leak. Another safety feature is a system of high-efficiency filters through which all air leaving the building must pass. These filters are designed to trap microscopic particles of radioactive materials that might otherwise be vented to the atmosphere. Other specialized devices and systems have also been developed for dealing with other kinds of accidents in various parts of the power plant.

Overall, a nuclear power plant can be considered to be similar to a conventional thermal power plant: Each type uses steam to drive a turbine generator that produces electricity. The heat energy of the steam is converted to mechanical energy in the turbine, and the generator then converts the mechanical energy into electrical energy, or electricity. Although the turbine functions equally well no matter where the steam comes from, the origin of the steam is important.

In terms of the production of steam, conventional plants burn natural gas, crude oil, or coal, and heat from the combustion of these fossil fuels boils water to make steam. In nuclear plants, on the other hand, no burning or combustion takes place and nuclear fission is used instead. The fission reaction generates heat, and this heat is transferred, sometimes indirectly, to the water that produces the steam. Consequently, it can be said that the fission reaction in a nuclear plant serves the same purpose – the generation of heat – as the burning of a fossil fuel in a conventional plant. The fission process requires a particular kind of a high atomic number element, such as uranium or plutonium, as a basic material.

For example, naturally-occurring uranium is a mixture of three isotopes, atomic forms that are chemically alike but vary in mass. An atom of one of these isotopes, uranium-235 (^{235}U), can readily undergo fission when a free neutron (an energetic subatomic particle) strikes its heavy central nucleus. The nucleus breaks into two pieces that fly apart at high speed; in addition, two or three new neutrons are released. Thus:

The kinetic energy of the fission fragments is converted to heat when they collide with surrounding atoms, and the released neutrons cause a chain reaction by initiating new fissions in other atoms of uranium.

Sustaining the chain reaction is important because more than 30 billion fissions must occur in one second to release each watt of energy. If the chain reaction is to be useful, the fissions must occur at a desired rate, and the heat that is generated by the process must be removed. Thus, the nuclear reactor provides an environment in which fission reactions can be initiated, sustained, and controlled, and to make possible recovery of the resultant heat.

The essential components of a reactor are: (i) the fuel, which fissions to produce neutrons and to release energy, (ii) the control elements, which are used to set the energy release rate, and (iii) the cooling fluid, which removes the heat generated in the reactor.

See also: Nuclear Reactor, Radioactivity, Steam Turbine.

Nuclear Reactor

A nuclear reactor is a reactor design for nuclear reactions in order to achieve a self-sustained chain reaction with a combination of fissile, fertile, and other materials. Common characteristics useful for classification purposes are (i) the coolant, which is the principle heat removal medium, (ii) the *steam cycle*, which is the number of separate coolant loops, (iii) the *moderator*, which is the material (if any) used to decrease the speed of neutrons produced by fission, (iv) the neutron energy, which is the general energy range for the neutrons that cause most of the fission reactions, and (v) the *fuel production system*, which is referred to as a breeder if the system produces more fuel than it consumes (i.e., the reactor changes from fissile to fertile) and, in such a case, the reactor is said to be a *converter*.

The first two features relate to the current practice of converting fission energy, first to heat and then to electrical energy by employing a steam cycle. Coolants include water, heavy water, gases, and liquid metals. The steam cycles may employ from one to three separate loops, including one for primary coolant circulation and one (not necessarily separate) for steam generation.

Since neutrons are emitted from fission at high energy and the very-low-energy neutrons have a higher likelihood of causing additional fission reactions. Thus, many systems employ a moderator to slow down these neutrons. The best moderators are of low mass, allowing maximum energy transfer through neutron collisions. Typical materials used for this purpose are hydrogen, deuterium (heavy hydrogen, hydrogen-2, ^2H), and carbon. The moderator and coolant may be the same (e.g., water) or may be separate materials (e.g., gaseous coolant and solid graphite moderator). Neutrons with low enough energies to be roughly in thermal equilibrium with the surrounding materials are said to be thermal neutrons, while neutrons at or near fission energies are termed fast neutrons. Fast reactors avoid the use of moderators, such as with a metal coolant like sodium, instead of one of the moderating materials identified above.

Any reactor that contains fertile species such as thorium-232 (^{232}Th), uranium-238 (^{238}U), or plutonium-242 (^{242}Pu) produces some amount of new fissile fuel. Breeder reactors actually produce more fuel than they consume, while converter reactors produce lesser amounts of new fuel.

The various types of nuclear reactor technologies (Table N-4) which all have several components in common such as the fuel, control rods, moderator, and coolant.

Table N-4 Types of nuclear reactors.

Type	Fuel	Moderator	Coolant
CANDU	Uranium	Heavy water*	Heavy water* under pressure
RBMK	Enriched uranium	Carbon (graphite)	Boiling water
BWR	Enriched uranium	Boiling water	Boiling water
PWR	Enriched uranium	Pressurized water**	Pressurized water
Fast reactor	Enriched uranium	None***	Liquid sodium****
Key: CANDU: Nuclear technology developed in Canada. RBMK: Bolchoe molchnastie kipiachie reactor – high-power boiling water reactor. BWR: Boiling water reactor. PWR: Pressurized water reactor.			

*Heavy water – deuterium oxide (D_2O) - water in which the hydrogen atoms of the water molecule (H_2O) have been replaced by deuterium, a heavy isotope of hydrogen.

**In liquid form.

***Neutrons remain fast.

****Does not slow down the neutrons.

Thus, a nuclear reactor is simply a device for starting and controlling a self-sustaining fission chain reaction from which energy for commercial and domestic activities can be produced:

Nuclear reactor	Heat	Electricity
		Hot water
		Hydrogen
		Steam

Nuclear reactors are used in several ways: (i) to supply intense fields or beams of neutrons for scientific experiments, (ii) to produce new elements or materials by neutron irradiation, and (iii) to furnish heat for electric power generation, propulsion, industrial processes, or other applications. There are various types of reactor technologies. Nonetheless, these nuclear reactors all have several components in common such as the fuel, control rods, moderator, and coolant.

The basic parts of a nuclear reactor are (i) the core of fuel, (ii) a neutron moderator which is a material that aids the fission process by slowing down the neutrons so they can collide with the atoms and provoke fission reactions, (iii) a means of regulating the number of free neutrons and thereby controlling the rate of fission, (iv) a means of removing the heat generated in the core, which is typically the purpose of the coolant water, and (v) radiation shielding.

Typically, the reactor containment is made of steel and/or reinforced concrete. It contains the reactor vessel, the primary system, the steam generators, and the main components important to reactor safety. It is leak-tight and designed to prevent leaks from radioactive fuel elements into the environment, particularly in the case of a severe accident like a core meltdown (strong rise in the temperature causing the fuel to melt).

The energy released as heat during the fission of uranium-235 nuclei must be transferred from the reactor core to the systems designed to transform heat into electricity, i.e., the turbine and alternator. This role is guaranteed by the coolant, the fluid used to remove the heat generated by the nuclear fuel. The coolant can be water, a liquid metal (sodium or lead), or a gas (carbon dioxide or helium). The coolant is also used to maintain the fuel temperature at its nominal temperature that is compatible with the resistance of the materials.

A heat exchanger is designed to transfer thermal power from one system to another. In the case of pressurized water reactors (PWRs), for instance, the primary coolant is water which exits the reactor core at a temperature on the order of 330°C (525°F) and is kept at a high pressure on the order of approximately 2,200 psi bar to prevent it from transforming into steam. This water then flows through a steam generator that is used to transfer the thermal power between the primary and secondary systems. They are designed so that the water in the secondary system boils and generates steam. When the steam expands, it drives a turbine that is coupled to an alternator which produces electricity. This system is also known as a power conversion system; thermal energy is converted into mechanical and then electrical energy. A third system is designed to cool and then condense steam.

Evolving from conventional water-cooled reactors, supercritical water-cooled reactor operates at high pressures, above the critical point, to allow for high coolant exit temperatures (up to 625°C, 1,155°F) and high thermal efficiencies. Such a temperature level is suitable for medium temperature process heat applications. Since water systems operate at elevated pressures, intermediate systems will be needed to convert thermal energy to lower pressure fluids used in industrial applications. All of the water-cooled concepts can be used for bottoming cycles that include district heating and desalination.

Gas-cooled reactor concepts include the pebble bed reactor and the prismatic modular reactor. Helium pressures enhance the coolant capacity to transmit heat. The coated particle fuel used in the thermal spectrum concepts is capable of high burnups, and they are easily adjustable to a wide range of fuel cycles. In terms of liquid metal-cooled reactor concepts. Closed fuel cycles are employed for the purpose of maximizing the uranium resource utilization and minimizing the amount of high-level radioactive waste.

In the case of sodium-cooled fast reactors (SFRs), the primary coolant is sodium, which is a liquid metal that exits the core at approximately 550°C (1,020°F) and at low pressure (typically, <100 psi). The power conversion system is based on the same principle as that of a pressurized water reactors insofar as a steam generator produces steam which expands in a turbine coupled to an alternator. The key difference is an additional system interposed between the primary system containing low-pressure sodium and the water-to-steam power conversion system at high pressure. The objective of this intermediary system is to take into account the risk of interaction between sodium and

water by dissociating the radiological risk in the primary system from other risks. Two heat exchangers are therefore required between the primary system and the power conversion system. The fast reactors have the advantage of saving on uranium resources and recycling recoverable materials, plutonium in particular.

Finally, as an additional note as an explanation of the nomenclature currently in use, considering the operating lifetimes of such facilities, reactors belonging to different generations can be defined.

The first generation includes the prototypes and the first industrial-scale reactors used for commercial purposes that were developed in the 1950s and 1960s before being commissioned in the 1970s. During this period, France developed a reactor technology using natural uranium for the fuel since it did not have access to uranium enrichment technologies.

The second generation of nuclear reactors was commissioned from early 1970 onwards. This generation was designed with objectives of improved competitiveness and energy independence at a time when tensions were running high due to the price of fossil fuels (oil crisis). Most of the reactors in current service are second generation.

The third generation focuses on safety and security requirements: consolidated resistance to external hazards such as plane crashes. These reactors have incorporated operating experience from second-generation reactors, from the Three Mile Island and Chernobyl accidents.

The fourth generation refers to reactors currently in design phase which could be deployed on an industrial scale by around 2050. The design incorporates a number of technological breakthroughs with respect to what has been built, and the criteria to be met (in addition to economic considerations) are: (i) sustainability, (ii) nuclear safety, and (iii) resistance to nuclear proliferation.

Nuclear Reactor – Boiling Water Reactor

In the boiling water reactor, water enters the reactor and is heated as it passes up between the elements of nuclear fuel. Soon, steam collects in the upper portion of the reactor and leaves through an outlet pipe. The pipes identified as steam pipes, and water pipes would be connected to those similarly to form a complete power plant.

The water and steam in a typical boiling-water reactor are kept at a pressure of 1,000 pounds per square inch (psi); this is equivalent to the pressure at a depth of approximately one-half mile beneath the surface of the sea. The pressure raises the boiling point of the reactor water to a high value, so that when steam is produced, its temperature and pressure are great enough for efficient use in the turbine.

Steam at the boiling temperature (100°C, 212°F) has too low an energy value for use in a turbine, and in order to increase the energy, the steam temperature must be raised. In a reactor, this is done by operating it at high pressure. At the typical boiling-water reactor pressure of 1,000 psi, the temperature of the steam is on the order of approximately 285°C (545°F). A nuclear steam-supply system based on a boiling-water reactor may appear relatively simple compared with some of the other systems. While the boiling-water system has only a few principal components, these are much larger than those in a pressurized-water system, for example. A central station nuclear power plant with an electrical output of around 800,000 kilowatts requires a boiling-water reactor vessel (the container that holds the nuclear fuel) approximately 70 feet high by 20 feet in diameter. A pressurized-water reactor vessel for a plant of the same capacity is only approximately 40 feet high by 16 feet in diameter. However, there are some additional large components in the pressurized-water system.

Nuclear Reactor – Breeder Reactor

A breeder reactor is a nuclear reactor that has the potential for breeding (i.e., producing more nuclear fuel than the reactor consumes) because of the materials, or combinations of materials, that are used to build the reactor.

For example, a uranium-235 atom can fission when its nucleus absorbs a neutron. The fission reaction releases free neutrons that may, in turn, initiate other fissions. All the neutrons released, however, are not absorbed by fissionable material; some are absorbed in the structural material of the reactor, the control elements, or the coolant; some escape from the reactor and are absorbed by shielding; and some are absorbed by fertile material. When the nucleus of an atom of fertile material absorbs a neutron, the fertile atom can be transformed into an atom of a fissionable

material – the substance that forms the basis for the nuclear chain reaction. By careful selection and arrangement of materials in the reactor—including, of course, fissionable and fertile isotopes – the neutrons not needed to sustain the fission chain reaction can fairly effectively convert fertile material into fissionable material.

The breeder reactor improves the efficiency of the neutron process both by increasing the number of free neutrons released in fission and by decreasing the number of neutrons wasted, thereby making a larger number available for absorption in fertile material. If, for each atom of fissionable material that is consumed, more than one atom of fertile material becomes fissionable material, the reactor is said to be breeding. One fertile material is uranium-238, which is always found in nature with fissionable uranium-235. When uranium-238 absorbs neutrons, it is converted to fissionable plutonium-239. Another fertile material is thorium-232, which can be converted to fissionable uranium-233.

Some of the reactors that are *possible* breeders may not prove capable of breeding in actual practice, but one type has already operated successfully in several plants. This is the liquid-metal-cooled breeder reactor.

Systems and components for the breeder reactor differ from those for other types of reactors. Both the primary reactor coolant system and the intermediate loop use liquid metal because it has excellent heat-transfer and nuclear characteristics; the metal is usually sodium. The liquid metal in the reactor is heated to approximately 535°C (1,000°F), and then goes to the heat exchanger, where it transfers its heat to the liquid metal of the intermediate loop. The metal in the intermediate loop moves to the steam generator, where it heats water to produce steam at a temperature on the order of 480°C (900°F).

Like other coolants, liquid metal has some desirable and some undesirable features. It is good because it does an excellent job of neutron conservation and of removing heat and does not have to be used at high pressure to attain high temperatures. The fuel in a liquid-metal-cooled breeder reactor can be operated at very high-power densities because the heat can be removed readily.

Nuclear Reactor - Decommissioning

Like other types of power plants, nuclear power plants have a lifespan after which they must be retired because the cost of running them becomes too high. The generation of nuclear power plants currently operating was designed to last approximately thirty years. Some plants showed serious levels of deterioration after as few as fifteen years. However, some have lasted well beyond thirty-year expectations. Whenever a power plant—whether coal, natural gas, or nuclear—is retired, it must be demolished and cleaned up so that the site can be used again.

Thus, at some point, the nuclear plants now operating worldwide may need to be retired. Most of them were designed to last approximately thirty years. Some plants showed serious levels of deterioration after as few as fifteen years; some have lasted well beyond their thirty-year expectations. There are three methods of retiring, or decommissioning, a reactor: (i) safe enclosure, (ii) entombment, and (iii) immediate dismantling.

Safe enclosure, or mothballing, involves removing the fuel from the plant, monitoring any radioactive contamination (which is low or nonexistent), and guarding the structure to prevent anyone from entering until eventual dismantling and decontamination activities occur. Entombment, which was used at Chernobyl, involves permanently encasing the structure in a long-lived material such as concrete. This procedure allows the radioactive material to remain safely on-site. Immediate dismantling involves decontaminating and tearing down the facility within a few months or years. This method is initially more expensive than the other options but removes the long-term costs of monitoring both the structure and the radiation levels. It also frees the site for other uses, including the construction of another nuclear power plant. Nuclear power companies are also seeking alternative uses for nuclear shells, including the conversion of old nuclear plants to gas-fired plants.

Nuclear Reactor – Fast Neutron Reactor

A fast-neutron reactor (FNR) or simply a fast reactor is a category of nuclear reactor in which the fission chain reaction is sustained by fast neutrons (carrying energies above 0.5 MeV or greater), as opposed to thermal neutrons

used in a thermal neutron reactor. This type of reactor does not need a neutron moderator but requires a fuel that is relatively rich in fissile material when compared to that required for a thermal neutron reactor.

A fast-neutron reactor can reduce the total radiotoxicity of nuclear waste by using all or almost all of the waste as fuel. With fast neutrons, the ratio between splitting and the capture of neutrons by plutonium and the minor actinide elements is often larger than when the neutrons are slower, at thermal or near-thermal epithermal speeds.

The transmuted even-numbered actinide elements (such as ^{240}Pu , ^{242}Pu) split nearly as easily as odd-numbered actinides in fast reactors. After they split, the actinides become a pair of fission products which have a reduced total radiotoxicity. Since disposal of the fission products is dominated by the most radiotoxic fission products strontium-90 (^{90}Sr), which has a half-life of 28.8 years, and caesium-137 (^{137}Cs) which has a half-life of 30.1 years, the result is to reduce nuclear waste lifetimes from tens of millennia (from transuranic isotopes) to a few centuries. The processes are not perfect, but the remaining transuranic elements are reduced from a significant problem to a tiny percentage of the total waste, because most of the transuranic elements can be used as fuel.

A fast reactor technically solves the fuel shortage without assuming undiscovered reserves, or extraction from dilute sources such as granite or seawater. They permit nuclear fuels to be bred from almost all the actinides, including known, abundant sources of depleted uranium and thorium, and light-water reactor wastes. On average, more neutrons per fission are produced by fast neutrons than from thermal neutrons. This results in a larger surplus of neutrons beyond those required to sustain the chain reaction. These neutrons can be used to produce extra fuel, or to transmute long half-life waste to less troublesome isotopes, or some can be used for each purpose. Though conventional thermal reactors also produce excess neutrons, fast reactors can produce enough of them to breed more fuel than they consume.

Nuclear Reactor – Gas-Cooled Reactor

The flow scheme for a gas-cooled reactor in bears a strong resemblance to the diagram for a pressurized-water reactor. The principle of operation is the same for both types of reactor insofar as a working fluid transports heat from the reactor to the steam generator, where the heat makes steam for the turbine.

In a gas-cooled reactor, the working fluid is a gas, usually helium or carbon dioxide at a pressure of a several hundred psi, is circulated through the reactor, the piping, and the steam generator by a blower (fan). The energy required to drive the blowers (there would be several) for the reactor of an 800,000-kilowatt power plant would operate 400,000 20-inch window fans. Also, there is a moderator which is a substance put in a reactor to slow the neutrons and increase the effectiveness in causing fissions. In water-cooled reactors, it is not necessary to add solid moderator components, because the cooling water serves this purpose. Gas is not a good moderator; however, in gas-cooled reactors, a special material, usually graphite, is built in. Graphite is a natural choice because it can withstand the high temperatures that exist in gas-cooled reactors (in some, the gas is heated to approximately 760°C ($1,400^{\circ}\text{F}$)). The high operating temperatures are put to good use. Steam as hot as approximately 535°C ($1,000^{\circ}\text{F}$) is produced; at this temperature and at the high pressure that goes with it, the steam can drive a turbine.

In addition to the high-temperature performance, a gas-cooled reactor has the desirable characteristic of low net fuel consumption; very advanced models, in fact, may be able to produce more fuel than they consume.

Nuclear Reactor – Heavy Water Reactor

Heavy water (D_2O) is usually used in tube-type reactors, in which the nuclear fuel is positioned inside process tubes that penetrate a tank. The tank contains the heavy water, which surrounds the fuel-containing tubes and acts as a moderator, much as graphite does in gas-cooled reactors. The fuel is in a form that does not occupy all the space in the process tubes, so there is room for a cooling fluid to flow along the fuel elements and remove the heat that is generated.

Any of several cooling fluids – organic compounds, gas, water, or heavy water – can be used in heavy-water reactors, since the heavy-water moderator is separated from the cooling fluid by the walls of the process tubes.

Temperatures in heavy-water reactors depend upon the kind of cooling fluid used, among other things, but steam hotter than 370°C (700°F) can be produced.

In terms of nuclear fuel utilization, the heavy-water reactor is an interim type: Its net fuel consumption is quite low, and it can operate on natural uranium, which makes it attractive to use in some countries.

Nuclear Reactor – Pressurized Water Reactor

A pressurized-water reactor operates at conditions under which the water passing through the reactor does *not* boil. Pressure in the reactor and the piping loop connected to it is on the order of 2,250 psi, or more than twice the pressure in a boiling-water reactor. This high pressure permits the water to be heated to 315°C (600°F) without boiling. The heated water goes to a steam generator that, as the name implies, makes the steam that drives the turbine.

In the steam generator, the hot reactor water passes through tubes that are surrounded by water from the turbine portion of the plant; this water is at a pressure well below that of the reactor water system. The tubes containing hot reactor water heat the surrounding water and make steam, which goes to the turbine at a temperature on the order of 260°C (500°F). The reactor water leaving the steam generator has been cooled by giving up some of this heat, so it is pumped through the reactor to be heated again and start another cycle.

A nuclear steam supply that uses a pressurized-water reactor consists of two separate water systems that meet in the steam generator. The water in one system does not mix with that in the other, but heat is transferred from the reactor system to the steam system.

Nuclear Safety

One of the issues that raise public concern related to anything connected with the term nuclear energy (or energy from nuclear sources) is the concern that a nuclear reactor might get out of control and melt down.

Unlike a fission power plant, which contains a large quantity of uranium or plutonium fuel, enough to keep it going for many years, a fusion power plant contains only a small amount of deuterium fuel (^2H or D_2) and tritium fuel (H^3 or T_3). Typically, there is approximately 1 gram of fuel which is sufficient to maintain the reaction for only a several few seconds, and if fuel is not continually replaced, the fusion reaction ceases.

A second consideration is the radioactive waste. A fission reactor produces two types of radioactive waste. The most difficult to process and store are the waste products that result from the fission fuel cycle – these are intensely radioactive substances that need to be separated from the unused fuel and then stored safely for tens of thousands of years. The fusion fuel cycle produces none of these radioactive waste products – the waste product is helium gas, which is not toxic or radioactive. The tritium fuel itself is radioactive, but it decays relatively quickly (the half-life is 12.3 years). Moreover, all of the tritium fuel that is produced will be recycled quickly and burned in the power plant.

An important safety feature is that there need be no shipments of radioactive fuels into or out of the fusion plant. The raw materials necessary for the fusion fuel, lithium and water, are completely nonradioactive. There is enough lithium to last for at least tens of thousands of years and enough deuterium in the oceans to be truly inexhaustible. Moreover, these raw materials are widely distributed, making it impossible for anyone in the country to corner the market. More advanced types of fusion may be developed in the long term to burn only deuterium.

The second source of waste from a nuclear power plant is the structure of the reactor – this is made radioactive by the neutrons emitted during the nuclear reactions. Fusion and fission are broadly similar in this respect, and some components of the structure of a fusion power plant will become intensely radioactive. Components that have to be removed for repair or replacement will have to be handled using remote robots and stored inside massive concrete shields. However, the lifetime of these structural wastes is much shorter than that of fission fuel waste products. At the end of its working life, a fusion power plant will have to be shielded before it can be demolished.

Nuclear Waste Management

The single most troubling issue for the nuclear power industry is waste management. Nuclear wastes can be classified into two general categories, low-level wastes and high-level wastes. The former consist of materials that release a relatively modest level of radiation and/or that will soon decay to a level where they no longer present a threat to humans and the environment. Storing these materials in underground or underwater reservoirs for a few years or in some other system is usually a satisfactory way of handling these materials.

High-level wastes are a different matter. After a period of time, the fuel rods in a reactor are no longer able to sustain a chain reaction and must be removed. These rods are still highly radioactive, however, and present a serious threat to human life and the environment that can be expected to last for tens of thousands of years. These rods and any materials derived from them (as, for example, during chemical dismantling of the rods to extract their plutonium for the production of nuclear weapons or for use as a nuclear fuel), are considered high-level wastes.

Occidental Flash Pyrolysis Process

The Occidental Flash Pyrolysis process (originally called the Garrett process) was designed to pyrolyze coal particles at a temperature not in excess of 760°C (1,400°F) in an entrained system to produce a liquid product, char, and gas.

The process utilizes the concept of short residence time of the feed coal, thereby increasing the throughput of coal per unit of cross-sectional area with the subsequent higher production of liquid products. Milled and screened coal is transported to the reactor by hot nitrogen where recycled hot char heats the coal rapidly to 510 to 730°C (950 to 1,350°F). A portion of the char product is cooled (as product), but the remainder is heated in a partial oxidation (burning) process to raise its temperature to 650 to 925°C (1,200 to 1,700°F) for recycle to the reactor. Cyclones remove fine char particles from the pyrolysis overhead prior to quenching in the collector system. This system consists of two tar recovery stages and a vacuum flash unit. In the first recovery stage, the pyrolysis vapor is condensed by quenching at approximately 99°C (ca. 210°F) to remove the majority of the heavier constituents; cooling to approximately 25°C (80°F) in the second stage causes water and low-boiling oils to condense. The vacuum flash unit is employed to separate the higher boiling constituents into fractions of varying volatility.

The process can accept a diversity of organic feedstocks to produce as its liquid products and offers potential for use with various biomass feedstocks. The char and **pyrolysis** gas produced as by-products are burned on-site for **process** heat.

Ocean Currents

Currents exist at all depths in the ocean; in some regions, two or more currents flow in different directions at different depths. Although the current system is complex, ocean currents are driven by two forces: the Sun and the rotation of the Earth.

The Sun affects the ocean in two ways. First, the Sun heats the atmosphere, creating winds and moving the sea surface through friction which tends to drag the water surface along as the wind blows over it. Although the wind strongly affects the surface layer, its influence does not extend much below approximately 325 feet in depth. Second, the Sun alters the density of the ocean surface water directly by changing its temperature and/or the salinity. If water is cooled or becomes saltier through evaporation, it becomes denser. This can result in the water column becoming unstable, setting up density-dependent currents, also known as the thermohaline circulation.

The rotation of the Earth also affects the currents through the Coriolis force which causes water to move to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. It exists because moving ocean water is affected by friction with the Earth only at the seafloor, and because the eastward linear velocity of the Earth decreases from a maximum at the equator to zero at the poles (the rotational velocity, however, does not change). A parcel of water at the equator is moving at the same speed as the Earth. If it starts to move north, with no friction, it is then going faster than the Earth beneath it. To conserve momentum (the product of mass and velocity), it consequently moves more to the east as it gets farther from the equator. The Coriolis force therefore increases away from the equator.

Patterns of Surface Currents

The movement of sea water between layers of varying temperature and density. Ocean circulation is produced by convection, with warm currents traveling away from the Equator, cooler water moving from the poles. In the Southern Hemisphere, the oceanic currents move in an anti-clockwise system, whereas in the Northern, the system is clockwise, an effect caused by the rotation of the Earth.

The general pattern of surface currents shows a series of quasi-circular gyres (circular or spiral motions or forms), or large eddies, in each ocean basin. The gyres tend to be biased toward the western side of the basin, where strong, narrow

flows are found in the Gulf Stream current, the Kuroshio current, the Agulhas current, the Brazilian current, and East Australian current, which flow at speeds up to 6 miles per hour. Current speeds away from the western boundaries of the gyres are generally much lower, and currents on the eastern boundaries of ocean basins are much wider.

The gyres rotate clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere because of the Coriolis force; in this, they follow the prevailing wind patterns. The gyres in both ocean and atmosphere help to transport heat away from the equator toward the poles (the Gulf Stream keeps northern Europe considerably warmer than its latitude suggests). This northward flow of warm water in the North Atlantic and a similar flow (the Kuroshio) in the North Pacific are partly balanced by southward flow in the East Greenland and Labrador Currents and in the Oyashio, respectively, while additional southward flow occurs at greater depths. The surface equatorward flow along the eastern edges of the gyres is also considerably cooler than the poleward flow found on the western boundaries. This results from wind-driven upwelling; the equatorward wind stress caused by the trade winds push water away from the coast and cooler subsurface water upwells to replace it.

Gyral motion is also absent near the equator. Equatorial currents are also driven by the wind, in particular by the trade winds – from the northeast in the Northern Hemisphere and from the southeast in the Southern Hemisphere. However, the Coriolis force here is zero, even though it becomes significant within one degree of latitude north or south. The boundary between the two sets of trade winds is usually slightly north of the equator. The trade winds set up two westward-flowing currents north and south of the equator (the North and South Equatorial Currents), but because the southeast trades blow across the equator, this causes a divergence (upwelling) along the equator itself because of the change in direction of the action of the Coriolis force.

Between the two trade-wind belts is a region of generally light winds, known as the Doldrums. This allows water, which would otherwise pile up against the western boundary of the ocean in the Equatorial currents, to flow back eastwards in the surface Equatorial Countercurrent. There is also an eastward-flowing equatorial undercurrent, which forms a jet within the thermocline, driven by the horizontal pressure gradient. This system of eastward-flowing and westward-flowing currents is found in the upper 650 feet in all three oceans, although their distribution may change seasonally.

Deep Currents

Currents in the deep ocean exist because of changes in the density of sea water occurring at the surface. These density changes give rise to specific water masses, which have well-defined temperature and salinity characteristics, and which can be traced for long distances in the ocean.

When sea water freezes, much of the salt that it contains is frozen out, so that a layer of cold brine forms at the ocean surface. Being denser than the water below it, the brine sinks, entraining water as it does so, until it reaches a level where it has the same density as the surrounding sea water. This process takes place in several regions of the world's oceans, the most important being in the Greenland, Norwegian, and Labrador Seas in the Northern Hemisphere, and close to the Antarctic continent in the Weddell and Ross Seas in the south.

Role of Water Masses

All these water masses help to transfer oxygen from the atmosphere into the deep ocean. The sinking water is very cold and contains high concentrations of dissolved oxygen acquired at the surface, because cold water can hold more oxygen than warm water. During their flow, they mix with “older” water that has been away from the surface for a longer time, thus ensuring that the bottom waters of the ocean are supplied with oxygen. Additional oxygen is supplied in the southern hemisphere by Antarctic Intermediate Water, formed in a band near 50° S to 55° S latitude. In this region, water does not freeze in winter, but it does cool forming a low salinity layer that sinks to approximately 1,000 meters (0.6 mile) depth and moves north in all three oceans.

Ocean Energy

The ocean can produce two types of energy: (i) thermal energy from the heat of the Sun and (ii) mechanical energy from the tides and waves. The heat of the Sun warms the surface water a lot more than the deep ocean water, and this temperature difference creates thermal energy.

There are three types of electricity conversion systems: (i) the closed-cycle system, (ii) the open-cycle system, and (iii) the hybrid system. Closed-cycle systems use the ocean's warm surface water to vaporize a working fluid, which has a low-boiling point, such as ammonia. The vapor expands and turns a turbine which then activates a generator to produce electricity. Open-cycle systems actually boil the seawater by operating at low pressures which produces steam that passes through a turbine/generator. A hybrid system combines both closed-cycle and open-cycle systems.

Ocean mechanical energy is different from ocean thermal energy. Even though the sun affects all ocean activity, tides are driven primarily by the gravitational pull of the moon, and waves are driven primarily by the winds. As a result, tides and waves are intermittent sources of energy, while ocean thermal energy is fairly constant. Also, unlike thermal energy, the electricity conversion of both tidal and wave energy usually involves mechanical devices.

The three most developed technologies derive (i) energy from tides, (ii) energy from waves, and (iii) ocean thermal energy conversion (OTEC) and are described below.

Tidal Energy

Tidal power is not a new concept, and has been used since the eleventh century to turn water wheels. Presently, power is generated from tides in a manner similar to hydroelectric power plants. In the process of deriving energy from tides, a dam (sometimes referred to as a barrage) is built across an estuary with gates, and turbines installed at regular intervals along the barrage are opened when there is significant difference in water elevation on either side of the barrage. Water flows through the turbines, and electricity is produced. This method can be used for water flowing both into and out of the estuary.

Although tidal power generation can offer some advantages, including reducing greenhouse gas emissions by not using fossil fuels, there are some significant environmental disadvantages. The construction of a tidal dam in an estuary will change the tidal level in the basin. This change will have a marked effect on the turbidity (cloudiness) of the water and sedimentation within the basin, which in turn affects navigation and recreation. An altered tidal level will also have an effect on the local marine food chain. However, because very few tidal barrages have been built, little is understood about the full impact of tidal power systems on the local environment, and it is evident that its effects greatly depend on the local geography and marine ecosystem.

Wave Energy

Wave energy generation devices fall into two general classifications: fixed and floating. Fixed generating devices, which are mounted either to the seabed or shore, have some significant advantages over floating systems, particularly in the area of maintenance. However, the number of suitable sites available for fixed devices is limited.

The oscillating water column, a fixed device built on shore, generates electricity in a two-step process. As a wave enters and leaves the column, the water in the column rises and falls, which in turn forces air back and forth through a turbine at the top of the column. This is a simple device, but it is difficult to build and anchor so that it is able to withstand the roughest sea conditions and yet generate a reasonable amount of power from small waves.

Another fixed device, the tapered channel system (TAPCHAN), consists of a tapered channel that feeds into a reservoir constructed on a cliff. The narrowing of the channel causes the waves to increase their amplitude (wave height) as they move toward the cliff face. The waves eventually break over the walls of the channel and into a reservoir, which is positioned several meters above mean sea level. The stored water in the reservoir is then fed through a turbine and generates electricity in the manner of an hydroelectric dam.

Floating-wave energy devices generate electricity through the harmonic motion of the floating part of the device, and are extremely efficient. In these systems, electricity is generated through the rise and fall of the waves.

There are three types of ocean thermal energy conversion processes: closed-cycle, open-cycle, and hybrid-cycle. In the closed-cycle system, heat transferred from the warm surface sea water causes a "working fluid" (such as ammonia, which boils at a temperature of approximately 25°C (77°F), at atmospheric pressure) to turn to vapor. The expanding vapor drives a turbine attached to a generator that produces electricity. The working fluid passes through a condenser and turns back into a liquid that is then recycled through the system.

Ocean Thermal Energy Conversion

The open-cycle ocean thermal energy conversion (OTEC) process uses the warm surface water itself as the working fluid. The water vaporizes in a near vacuum at surface water temperatures. The expanding water vapor drives

a turbine attached to a generator and produces electricity. The water vapor, which has lost its salt and is almost pure fresh water, is condensed back into a liquid by exposure to cold temperatures from deep-ocean water. If the condenser keeps the vapor from direct contact with sea water, the condensed water can be used for drinking water, irrigation, or aquaculture. A direct contact condenser produces more electricity, but the vapor is mixed with cold sea water and the discharge water is salty and is returned to the ocean. The process is repeated with a continuous supply of warm surface sea water. Hybrid systems use parts of both open-cycle and closed-cycle systems to optimize the production of electricity and fresh water.

Octane Number

The gasoline performance and hence quality of an automobile gasoline is determined by its resistance to knock, for example, *detonation* or *ping* during service. The antiknock quality of the fuel limits the power and economy that an engine using that fuel can produce: the higher the antiknock quality of the fuel, the more the power, and efficiency of the engine.

In the early days of automobile engine development, there was a demand for more powerful engines and knocking was not a problem. This demand for more powerful engines was met at first by adding more and larger pistons to the engines; some were even built with 16 cylinders. However, the practical limit to the size to which an engine could be built meant that other avenues to increased power had to be explored. The obvious method of getting more power from an engine of given size was to increase its compression ratio (a measure of the extent to which the gasoline-air mixture is compressed in the cylinder of an engine). The more the mixture is compressed before ignition, the more power the engine can deliver, but the increased performance was accompanied by an increased tendency for detonation or *knocking*. Eventually, the cause of engine knock was traced to the gasoline. Since some gasolines seemed to cause more knock than another, and since there was no suitable testing procedure, it was difficult to determine the relative antiknock characteristics of gasoline. It appeared, however, that cracked gasoline caused less knock than straight-run gasoline and, hence, the use of cracked gasoline as a fuel increased.

In 1922, tetraethyl lead was discovered to be an excellent antiknock material when added in small quantities to gasoline, and gasoline containing tetraethyllead became widely available. However, the problem of how to increase the antiknock characteristics of cracked gasoline became acute in the 1930s. One feature of the problem concerned the need to measure the antiknock characteristics of gasoline accurately. This was solved in 1933 by the general use of a single-cylinder test engine, which allowed comparisons of the anti-knock characteristics of gasoline to be made in terms of octane numbers. The octane numbers formed a scale ranging from 0 to 100: the higher the number, the greater the antiknock characteristics. In 1939, a second and less severe test procedure using the same test engine was developed, and results obtained by this test were also expressed in octane numbers.

Octane numbers are obtained by the two test procedures, those obtained by the first method are called *motor octane numbers* (indicative of high-speed performance) (ASTM D2700 and ASTM D2723). Those obtained by the second method are called *research octane numbers* (indicative of normal road performance) (ASTM D2699 and ASTM D2722). Octane numbers quoted are usually, unless stated otherwise, research octane numbers.

In the test methods used to determine the antiknock properties of gasoline, comparisons are made with blends of two pure hydrocarbon derivatives, *n*-heptane and *iso*-octane (2,2,4-trimethylpentane). *Iso*-octane has an octane number of 100 and is high in its resistance to knocking; *n*-heptane is quite low (with an octane number of 0) in its resistance to knocking.

The anti-knock characteristics of an additive are typically evidenced by an increase in the motor and research octane numbers of the base fuel when the additive is admixed therewith. The motor (MON) and research (RON) octane numbers of fuel compositions are typically measured by ASTM D 2700 and ASTM D 2699, respectively. While motor and research octane numbers are themselves good indicators of the anti-knock characteristics of an additive, another measure of the anti-knock characteristics of an additive is the average of the two numbers $(RON + MON)/2$. This average provides a fairly good approximation of the octane number required by engines under typical driving conditions, in that MON is a more severe test, with higher compression and temperature, than RON. Furthermore, this average is the typical rating used for commercial fuel products.

Extensive studies of the octane numbers of individual hydrocarbon derivatives have brought to light some general rules. For example, normal paraffins have the least desirable knocking characteristics, and these become progressively worse as the molecular weight increases. *Iso*-paraffins have higher octane numbers than the corresponding normal isomers, and the octane number increases as the degree of branching of the chain is increased. Olefins have markedly higher octane numbers than the related paraffin derivatives; naphthene derivatives are usually better than the corresponding normal paraffin derivatives but rarely have high octane numbers; aromatic derivatives usually have high octane numbers.

Blends of *n*-heptane and *iso*-octane thus serve as a reference system for gasoline and provide a wide range of quality used as an antiknock scale. The exact blend, which matches identically the antiknock resistance of the fuel under test, is found, and the percentage of *iso*-octane in that blend is termed the *octane number* of the gasoline. For example, gasoline with a knocking ability which matches that of a blend of 90% *iso*-octane and 10% *n*-heptane has an octane number of 90. However, many pure hydrocarbon derivatives and even commercial gasoline have an anti-knock quality above an octane number of 100. In this range, it is common practice to extend the reference values by the use of varying amounts of tetraethyllead in pure *iso*-octane.

With an accurate and reliable means of measuring octane numbers, it was possible to determine the cracking conditions – temperature, cracking time, and pressure – that caused increases in the antiknock characteristics of cracked gasoline. In general, it was found that higher cracking temperatures and lower pressures produced higher octane gasoline, but unfortunately more gas, cracked residua, and coke were formed at the expense of the volume of cracked gasoline.

To produce higher-octane gasoline, cracking coil temperatures were pushed up to 510°C (950°F), and pressures dropped from 1,000 to 350 psi. This was the limit of thermal cracking units, for at temperatures over 510°C (950°F), coke formed so rapidly in the cracking coil that the unit became inoperative after only a short time on-stream. Hence, it was at this stage that the nature of the gasoline-producing process was reexamined, leading to the development of other processes, such as reforming, polymerization, and alkylation for the production of gasoline components having suitably high octane numbers.

It is worthy of note here that the continued decline in crude oil reserves and the issue of environmental protection have emerged as of extreme importance in the search for alternatives to crude oil. In this light, oxygenates, either neat or as additives to fuels, appear to be the principal alternative fuel candidates beyond the crude oil refinery.

Octane Rating

The octane rating of a fuel is the knock resistance (anti-knock rating) compared to a mixture of *iso*-octane (2,2,4-trimethylpentane, an isomer of octane) and *n*-heptane. By definition, *iso*-octane is assigned an octane rating of 100 and heptane is assigned an octane rating of zero. An 87-octane gasoline, for example, possesses the same anti-knock rating of a mixture of 87% (by volume) *iso*-octane and 13% (by volume) *n*-heptane. This does not mean, however, that the gasoline actually contains these hydrocarbon derivatives in these proportions. It simply means that it has the same autoignition resistance as the described mixture.

The octane rating does not relate to the energy content of the fuel nor the speed at which the flame initiated by the spark plug propagates across the cylinder. It is only a measure of the resistance of the fuel to autoignition. It is for this reason that one highly branched form, or isomer, of octane (2,2,4-trimethylpentane) has (by definition) an octane rating of 100, whereas *n*-octane has an octane rating of -10, even though the two fuels have exactly the same chemical formula.

The most common type of octane rating worldwide is the Research Octane Number (RON) which is determined by running the fuel in a test engine with a variable compression ratio under controlled conditions, and comparing the results with those for mixtures of *iso*-octane and *n*-heptane.

The Motor Octane Number (MON) is a better measure of how the fuel behaves when under load. MON testing uses a similar test engine to that used in RON testing, but with a preheated fuel mixture, a higher engine speed, and variable ignition timing to further stress the knock resistance of the fuel. Depending on the composition of the fuel, the MON of a modern gasoline will be approximately 8 to 10 points lower than the RON. Normally, fuel specifications require both a minimum RON and a minimum MON.

The octane ratings of n-heptane and iso-octane are exactly 0 and 100, by definition. For some other hydrocarbon derivatives, the ratings are variable (Table O-1).

Table O-1 Octane ratings of various hydrocarbon derivatives in order of increasing rating.

Hydrocarbon	Octane rating
n-octane	-10
n-heptane	0
2-methyl heptane	23
n-hexane	25
2-methylhexane	44
1-heptene	60
n-pentane	62
1-pentene	84
n-butane	91
cyclohexane	97
iso-octane	100
benzene	101
Methane	107
Ethane	108
Toluene	114
Xylene	117

Using a fuel with a higher octane lets an engine run at a higher compression ratio without having problems with knock. Actual compression in the combustion chamber is determined by the compression ratio as well as the amount of air restriction in the intake manifold (manifold vacuum) as well as the barometric pressure, which is a function of elevation and weather conditions.

Oil-Bearing Plants

Oil-bearing plants are the plants which produce seeds that can be crushed on the farm to produce a range of vegetable oils, and although they are not good enough for human consumption, they can be used to power motors and onsite generators like those used for combined heat and power plants (CHP).

Oils, Fats, and Waxes

Oils, fats, and waxes are common constituents of plants and usually consist of terpene hydrocarbon derivatives and their derivatives or alcohols, acids, and esters.

Oils occur in much greater concentrations in fruits and seeds. The so-called essential oils are usually sweet, or aromatic-smelling organic compounds which may also contain sulfur and nitrogen in addition to the usual carbon

and hydrogen. These oils are often of the terpene class with the general formula $(C_5H_8)_n$, where $n > 1$, or may be compound types similar to camphor or other oxidation products associated with the basic terpene structure.

Alternately, oils found in plants may also be of the fatty acid or glyceride type or may even be esters of the higher monohydric alcohols and fatty acids. The acids most commonly found as glycerides, or esters in plants are:

$C_{15}H_{31}COOH$	Palmitic acid
$C_{17}H_{35}COOH$	Stearic acid
$C_{17}H_{33}COOH$	Oleic acid

In the glycerides, any of the above fatty acids can combine with glycerol to yield a symmetrical glyceride in which the acid radicals are the same:

$CH_2OCOC_{15}H_{31}$	$CH_2OCOC_{17}H_{35}$
$CHOCOC_{15}H_{31}$	$CHOCOC_{17}H_{35}$
$CH_2OCOC_{15}H_{31}$	$CH_2OCOC_{17}H_{35}$
Tripalmitin	Tristearin

Different fatty acids may combine with one molecule of glycerin to produce a mixed glyceride, e.g.,:

$CH_2OCOC_{17}H_{35}$	$CH_2OCOC_{17}H_{35}$
$CHOCOC_{17}H_{35}$	$CHOCOC_{17}H_{35}$

Palmitodistearin	Oleodistearin

Vegetable oils and fats are usually liquids or semisolids at ambient temperature and may not actually possess a well-defined melting point. There are many other fatty acids (other than palmitic, stearic, and oleic acids) which are found in plant tissue which may have also been incorporated into the coal precursor, thereby complicating the contribution from the fatty acids still further.

A group of chemical compounds which falls under the general classification sterols also occurs in animal and plant oils and in fats. The structure of the sterols is based on the multi-ring perhydrocyclopentaphenanthrene skeleton.

Sterols are crystalline compounds and contain a hydroxyl group (e.g., cholesterol). They occur either in the uncombined form or as esters of the higher fatty acids and can be isolated from the unsaponifiable portion of oils and fats. Sterols (or the related compounds, the steroids) also occur in animal tissue. In these cases, the compound may actually be cholesterol or the hydroxyl group or the alkyl side chain may have been altered to afford a structurally related compound. The majority of the steroid-type material that contributed to the coal substance may not have arisen from animal remains and that the majority of the steroid-type material which eventually became part of the coal substance arose from plant debris.

Waxes often occur naturally as high-molecular-weight alcohols and esters, although free fatty acids may also occur within this group. The constitution of the natural waxes is a contrast to the so-called crude oil wax, which is actually a mixture of straight-chain paraffin hydrocarbon derivatives containing more than seventeen carbon atoms and which are also solid at room temperature but which do not contain any oxygen functional groups.

The structural chemistry of the natural waxes is somewhat less well defined than the structural chemistry of the oils and fats (glycerides). The more common straight-chain materials are defined by their names, e.g., octacosanol, 28-carbon alcohol, but there is still some doubt related to the structures of some of the less conventionally named natural waxes.

Okra

Okra (sometimes written as Okro, *Abelmoschus esculentus*), known in many English-speaking countries as ladies' fingers or ochro, is a flowering plant in the mallow family. Okra is a crop with considerable potential as an oil seed,

but the growth habits of most cultivars currently grown make harvesting for seed impractical. Okra ripens one pod at a time on each stalk over a period of 2 or 3 months. When ripe, the pods of most cultivars dehisce and most of the seeds either fall out or are rain damaged. The data show the potential for oil and oil seed meal production by okra. The yields of combine-harvested okra seed were only approximately 25% as great. Research by nutritionists has shown that okra meal may be useful as a human food source.

Olamine

An olamine is a compound such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) that is widely used in gas processing (Table O-2).

Ethanolamine (2-aminoethanol, monoethanolamine, ETA, or MEA) is an organic chemical compound with the formula $\text{HOCH}_2\text{CH}_2\text{NH}_2$ ($\text{C}_2\text{H}_7\text{NO}$). The molecule is bifunctional containing both a primary amine ($-\text{CH}_2\text{NH}_2$) and a primary alcohol function ($-\text{CH}_2\text{OH}$).

Table O-2 Olamines used for gas processing.

Olamine	Formula	Derived name	Molecular weight	Specific gravity	Melting point, C	Boiling point, C	Flash point, C	Relative capacity %
Ethanolamine	$\text{HOC}_2\text{H}_4\text{NH}_2$	MEA	61.08	1.01	10	170	85	100
Diethanolamine	$(\text{HOC}_2\text{H}_4)_2\text{NH}$	DEA	105.14	1.097	27	217	169	58
Triethanolamine	$(\text{HOC}_2\text{H}_4)_3\text{N}$	TEA	148.19	1.124	18	335, d	185	41
Diglycolamine	$\text{H}(\text{OC}_2\text{H}_4)_2\text{NH}_2$	DGA	105.14	1.057	-11	223	127	58
Diisopropanolamine	$(\text{HOC}_3\text{H}_7)_2\text{NH}$	DIPA	133.19	0.99	42	248	127	46
Methyldiethanolamine	$(\text{HOC}_2\text{H}_4)_2\text{NCH}_3$	MDEA	119.17	1.03	-21	247	127	51

d: with decomposition

Like other amines, monoethanolamine is a weak base and this property makes it favorable for gas scrubbing. Solutions of monoethanolamine (MEA) in water are used as a gas stream scrubbing liquid in amine treating units. For example, aqueous monoethanolamine is used to remove carbon dioxide (CO_2) and hydrogen sulfide (H_2S) from various gas streams. The monoethanolamine ionizes dissolved acidic compounds, making them polar and having an increased solubility. The monoethanolamine scrubbing solutions can be recycled through a regeneration unit. When heated, monoethanolamine (being a rather weak base) will release dissolved carbon dioxide gas or hydrogen sulfide gas, thereby regenerating the monoethanolamine.

See also: Gas Cleaning, Gas Processing, Gas Treating, Olamine Processes.

Olamine Processes

An olamine process is a process that uses an amine derivative (an olamine) to remove acid gas from natural gas streams.

Ethanolamine derivatives became available commercially in the early 1930s; they assumed steadily growing commercial importance as intermediates after 1945, because of the large-scale production of ethylene oxide. Since the mid-1970s, economical production of very pure, colorless ethanolamines has been possible. Ethanolamine derivatives are produced on an industrial scale exclusively by reaction of ethylene oxide and excess ammonia. This reaction takes place slowly, but is accelerated by water. An anhydrous procedure uses a fixed-bed ion-exchange resin catalyst.

Acid gas removal is an important process in various branches of the hydrocarbon processing industry, primarily in natural gas processing and refining. Acid gas removal is also an essential part of other processes, such as coal

gasification where carbon dioxide, hydrogen sulfide, carbonyl sulfide, mercaptan derivatives, and other contaminants need to be removed. Acid gas is defined as gas containing significant amounts of contaminants, such as hydrogen sulfide (H_2S), carbon dioxide (CO_2), and other acidic gases. Sour gas is gas contaminated with hydrogen sulfide, and, thus, gas sweetening refers to hydrogen sulfide removal, because it improves the odor of the gas being processed, while the term acid gas removal refers to the removal of both hydrogen sulfide and carbon dioxide. Acid gases need to be removed in order to comply with sales gas quality regulations. One such treatment for acid gas removal involves the use of ethanolamine derivatives, especially triethanolamine (TEA).

The most commonly used technique for gas processing is to first direct the gas flow through a tower containing an amine (olamine) solution. Amines absorb sulfur compounds from natural gas and can be reused repeatedly. After desulfurization, the gas flow is directed to the next section, which contains a series of filter tubes. As the velocity of the stream reduces in the unit, primary separation of remaining contaminants occurs due to gravity. Separation of smaller particles occurs as gas flows through the tubes, where they combine into larger particles which flow to the lower section of the unit. Further, as the gas stream continues through the series of tubes, a centrifugal force is generated which further removes any remaining water and small solid particulate matter.

The processes that have been developed to accomplish gas purification vary from a simple once-through wash operation to complex multi-step recycling systems. In many cases, the process complexities arise because of the need for recovery of the materials used to remove the contaminants or even recovery of the contaminants in the original, or altered, form.

The general process flow diagram for an amine sweetening plant varies little, regardless of the aqueous amine solution used as the sweetening agent. The sour gas containing hydrogen sulfide and/or carbon dioxide will nearly always enter the plant through an inlet separator (scrubber) to remove any free liquids and/or entrained solids. The sour gas then enters the bottom of the absorber column and flows upward through the absorber in intimate counter-current contact with the aqueous amine solution, where the amine absorbs acid gas constituents from the gas stream. Sweetened gas leaving the top of the absorber passes through an outlet separator and then flows to a dehydration unit (and compression unit, if necessary) before being considered ready for sale.

The primary process for sweetening sour natural gas is quite similar to the processes of glycol dehydration and removal of natural gas liquids by absorption. In this case, however, amine (*olamine*) solutions are used to remove the hydrogen sulfide (the *amine process*). The sour gas is run through a tower, which contains the olamine solution. There are two principle amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from natural gas as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status. Like the process for the extraction of natural gas liquids and glycol dehydration, the amine solution used can be regenerated for reuse.

Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) are the most widely used *olamines* in commercial applications. They are selected according to their relative ability to interact with and remove carbon dioxide and/or hydrogen sulfide.

The chemistry can be represented by simple equations for low partial pressures of the acid gases:

At high acid gas partial pressure, the reactions will lead to the formation of other products:

The reaction is extremely fast, the absorption of hydrogen sulfide being limited only by mass transfer; this is not so for carbon dioxide.

Regeneration of the solution leads to near complete desorption of carbon dioxide and hydrogen sulfide. A comparison between monoethanolamine, diethanolamine, and diisopropanolamine shows that monoethanolamine is the cheapest of the three amines but shows the highest heat of reaction and corrosion; the reverse is true for diisopropanolamine.

The processes using ethanolamine and potassium phosphate are now widely used. The ethanolamine process, known as the *Girbotol* process, removes acid gases (hydrogen sulfide and carbon dioxide) from liquid hydrocarbon derivatives as well as from natural and from refinery gases. The Girbotol process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower called an absorber through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

As currently practiced, acid gas removal processes involve the chemical reaction of the acid gases with a solid oxide (such as iron oxide) or selective absorption of the contaminants into a liquid (such as ethanolamine) that is passed countercurrent to the gas. Then, the absorbent is stripped of the gas components (regeneration) and recycled to the absorber. The process design will vary and, in practice, may employ multiple absorption columns and multiple regeneration columns.

Amine (olamine) washing of natural gas involves chemical reaction of the amine with any acid gases with the liberation of an appreciable amount of heat, and it is necessary to compensate for the absorption of heat. Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), diisopropanolamine (DIPA), and diglycolamine (DGA) have been used in commercial applications.

Processes that use methyl diethanolamine (MDEA) became popular with the natural gas industry because of its high selectivity for hydrogen sulfide over carbon dioxide. This high selectivity allows for a reduced solvent circulation rate, as well as a richer hydrogen sulfide feed to the sulfur recovery unit. The reaction of methyl diethanolamine with hydrogen sulfide is almost instantaneous. However, the reaction of methyl diethanolamine with carbon dioxide is much slower; the reaction rate of methyl diethanolamine with carbon dioxide is slower than that of carbon dioxide with ethanolamine.

Depending upon the application, special solutions such as mixtures of amines; amines with physical solvents such as sulfolane and piperazine; and amines that have been partially neutralized with an acid such as phosphoric acid may also be used.

A series of chemical activators used with methyl diethanolamine offers the most cost-effective answer to complete or controlled acid gas removal from sour to very sour natural gases. However, there are limitations of even the most advanced *activated methyl diethanolamine* only-based gas treatment technologies in handling very highly acid gas loaded natural or associated oil field gases, especially for bulk acid gas removal when the acid gases are destined for cycling and/or disposal by re-injection. The activated methyl diethanolamine process is a cost-effective solution that is available to meet the widest range of applications from complete carbon dioxide removal to bulk hydrogen sulfide and/or carbon dioxide removal even for acid gas re-injection projects.

Olefin Hydrocarbons

Unsaturated (lower ratio of hydrogen to carbon) compounds of carbon and hydrogen having at least one double bond. The presence of the double bond renders the alkene much more reactive than the corresponding alkane (Table O-3).

Table O-3 Reactions of olefin derivatives (alkenes).

Reaction name 	Product 	Comment
Hydrogenation	alkanes	addition of hydrogen
Halogen addition	1,2-dihalide	electrophilic addition of halogens
Hydrohalogenation	haloalkanes	addition of hydrohalic acids
Hydroamination	amines	addition of N-H bond
Hydroformylation	aldehydes	addition of CO and H ₂
Bishydroxylation	diols	oxidation, reagent: osmium tetroxide
Cis-hydroxylation	diols	oxidation, reagents: iodine, silver acetate
ozonolysis	aldehydes or ketones	reagent: ozone
Olefin metathesis	alkenes	two alkenes rearrange to form two new alkenes
Diels-Alder reaction	cyclohexenes	cycloaddition with a diene
Hydroboration-oxidation	alcohols	reagents: borane, then a peroxide
oxymercuration-reduction	alcohols	electrophilic addition of mercuric acetate, then reduction
Prins reaction	1,3-diols	electrophilic addition with aldehyde or ketone
Paterno-Büchi reaction	oxetanes	photochemical reaction with aldehyde or ketone
Epoxidation	epoxide	electrophilic addition of an peroxide
Cyclopropanation	cyclopropanes	addition of carbenes or carbenoids

Refinery gas streams also contain olefin constituents that are produced by various cracking processes, and some streams also contain varying amounts of other chemicals including, ammonia, hydrogen, nitrogen, hydrogen sulfide, mercaptan derivatives, carbon monoxide, carbon dioxide, 1,3-butadiene, and/or benzene.

Some gases may also contain inorganic compounds, such as hydrogen, nitrogen, hydrogen sulfide, carbon monoxide, and carbon dioxide. Many low-molecular-weight olefins (such as ethylene and propylene) and diolefins (such as butadiene) which are produced in the refinery are isolated for petrochemical use. The individual products are: (i) ethylene, (ii) propylene, and (iii) butadiene.

Ethylene (C₂H₄) is a normally gaseous olefinic compound having a boiling point of approximately -104°C (-155°F) which may be handled as a liquid at high pressure and low temperature. Ethylene is made normally by cracking an ethane or naphtha feedstock in a high-temperature furnace and subsequent isolation from other components by distillation. The major uses of ethylene are in the production of ethylene oxide, ethylene dichloride, and the polyethylene polymers. Other uses include the coloring of fruit, rubber products, ethyl alcohol, and medicine (anesthetic).

Propylene concentrates are mixtures of propylene and other hydrocarbons, principally propane and trace quantities of ethylene, butylenes, and butanes. Propylene concentrates may vary in propylene content from 70% mol up to over 95% mol and may be handled as a liquid at normal temperatures and moderate pressures. Propylene concentrates are isolated from the furnace products mentioned in the preceding paragraph on ethylene. Higher purity propylene streams are further purified by distillation and extractive techniques. Propylene concentrates are used in the production of propylene oxide, isopropyl alcohol, polypropylene, and the synthesis of isoprene. As is the case for ethylene, moisture in propylene is critical.

Butylene concentrates are mixtures of butene-1, cis- and trans-butene-2, and, sometimes, isobutene (2-methyl propylene) (C₄H₈).

These products are stored as liquids at ambient temperatures and moderate pressures. Various impurities such as butane, butadiene, and the C_5 hydrocarbons are generally found in butylene concentrates. The majority of the butylene concentrates are used as a feedstock for either: (i) an alkylation plant, where isobutane and butylenes are reacted in the presence of either sulfuric acid or hydrofluoric acid to form a mixture of C_7 to C_9 paraffins used in gasoline, or (ii) butylene dehydrogenation reactors for butadiene production.

Butadiene (C_4H_6 , $CH_2=CHCH=CH_2$) is a normally gaseous hydrocarbon having a boiling point of -4.38°C (24.1°F) which may be handled as a liquid at moderate pressure. Ambient temperatures are generally used for long-term storage due to the easy formation of butadiene dimer (4-vinyl cyclohexene-1). Butadiene is produced by two major methods: the catalytic dehydrogenation of butane or butylenes or both, and as a by-product from the production of ethylene. In either case, the butadiene must be isolated from other components by extractive distillation techniques and subsequent purification to polymerization-grade specifications by fractional distillation. The largest end use of butadiene is as a monomer for production of GR-S synthetic rubber. Butadiene is also chlorinated to form 2-chloro-butadiene (chloroprene) ($CH_2=CHCCl=CH_2$) that is a feedstock used to produce neoprene (a polychloroprene rubber).

The major quality criteria for butadiene are the various impurities that may affect the polymerization reactions for which butadiene is used. The gas chromatographic examination of butadiene (ASTM, 2017) can be employed to determine the gross purity as well as C_3 , C_4 , and C_5 impurities. Most of these hydrocarbons are innocuous to polymerization reactions, but some, such as butadiene-1,2 and pentadiene-1,4, are capable of polymer crosslinking.

Rotation around the carbon-carbon double bond ($-C=C-$) is restricted because it involves breaking the pi bond, which requires a large amount of energy. As a consequence, substituted alkenes may exist as one of two isomers: (1) a cis isomer and a trans isomer. For example, in cis-but-2-ene, the two methyl substituents face the same side of the double bond and in trans-but-2-ene, they face the opposite side; these two isomers are slightly different in their chemical and physical properties.

All the alkenes with 4 or more carbon atoms in them show *structural isomerism*. This means that there are two or more different structural formulae that can be drawn for each molecular formula. For example, with butene (C_4H_8), there are three structural isomers (Figure O-1):

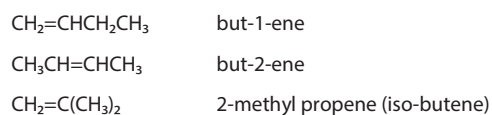

Figure O-1 Isomers of butene.

Butadiene (a diolefin, C_4H_6 , $CH_2=CHCH=CH_2$) is a normally gaseous hydrocarbon having a boiling point of $-4.38^\circ C$ ($24.1^\circ F$) which may be handled as a liquid at moderate pressure. Ambient temperatures are generally used for long-term storage due to the easy formation of butadiene dimer (4-vinyl cyclohexene-1). Butadiene is produced by two major methods: the catalytic dehydrogenation of butane or butylenes or both, and as a by-product from the production of ethylene. In either case, the butadiene must be isolated from other components by extractive distillation techniques and subsequent purification to polymerization-grade specifications by fractional distillation. The largest end use of butadiene is as a monomer for production of GR-S synthetic rubber. Butadiene is also chlorinated to form 2-chloro-butadiene (chloroprene) ($CH_2=CHCCl=CH_2$) that is a feedstock used to produce neoprene (a polychloroprene rubber).

The major quality criteria for butadiene are the various impurities that may affect the polymerization reactions for which butadiene is used. The gas chromatographic examination of butadiene (ASTM, 2017) can be employed to determine the gross purity as well as C_3 , C_4 , and C , impurities. Most of these hydrocarbons are innocuous to polymerization reactions, but some, such as butadiene-1,2 and pentadiene-1,4, are capable of polymer cross-linking.

Open Core Gasifier

The open core gasifier is a recent development of gasifier design for gasification of small-sized biomass with high ash content.

In the open core gasifier, the air is sucked over the whole cross section from the top of the bed. This facilitates better oxygen distribution since the oxygen will be consumed over the whole cross section, so that the solid bed temperature will not reach the local extremes (hot spots) observed in the oxidation zone of conventional gasifiers due to poor heat transfer. Moreover, the air nozzles in conventional gasifiers generate caves and create obstacles that may obstruct solid flow especially for solids of low bulk like rice husk.

On the other hand, the entry of air through the top of the bed creates a downward flow of the pyrolysis gases, and transports the tars products to the combustion zone. Thus, flow problems due to the caking of rice husk caused by back mixing of tar are avoided.

See also: Gasification, Gasification of Biomass.

Open-Loop Biomass

Open-loop biomass is biomass (such as cellulosic and lignin waste material) that can be used to produce energy and bioproducts even though it was not grown specifically for this purpose; includes agricultural livestock waste, residues from forest-harvesting, and crop-harvesting operations.

See also: Biomass, Cellulose, Lignin, Lignocellulose.

Organic Chemicals

The term organic chemicals includes a broad class of substances containing carbon and its derivatives. Many of these chemicals will frequently contain hydrogen with or without oxygen, nitrogen, sulfur, phosphorus, and other elements. They exist either in the form of a carbon chain or in the form of a carbon ring.

More specifically, organic chemicals are structurally diverse, and the range of application of organic chemicals is enormous. In addition, organic chemicals may contain any number of other elements, including nitrogen, oxygen, sulfur, halogens, phosphorus, and silicon. They form the basis of, or are important constituents of, many products (such as plastics, drugs, petrochemicals, food, explosives, and paints) and, with very few exceptions, they form the basis of all life processes and many industrial processes.

Organic compounds – of which the hydrocarbon derivatives are a sub-group – are classified according to the presence of functional groups in the molecule. A functional group is a molecular moiety that typically dictates the

behavior (reactivity) of the organic compound in the environment, and the reactivity of that functional group is assumed to be the same in a variety of molecules, within some limits and if steric effects (that arise from the three-dimensional structure of the molecule) do not interfere. Thus, most organic functional groups feature heteroatoms (atoms other than carbon and hydrogen, such as: nitrogen, oxygen, and sulfur). The concept of functional groups is major concept in organic chemistry, both to classify the structure of organic compounds and to predict the physical and chemical properties, especially, in the context of this book, those properties that relate to behavior and reactivity in technological processes.

Organic chemicals, from simple compounds such as methane (CH_4), to organic chemicals that contain more than one carbon atom, as many as ten carbon atoms to chemicals that contain hundreds or more carbon atoms that are linked in carbon-carbon bonds. Those that contain only carbon and hydrogen are called hydrocarbons; a simple example is $\text{H}_3\text{C}(\text{CH}_2)_3\text{CH}_3$ (pentane). Organic chemicals commonly contain other elements too, such as oxygen, nitrogen, or sulfur. An organometallic chemical has a carbon atom bonded to a metal as in tetraethyl lead. Some organometallic chemicals are found naturally.

Many organic chemicals are synthetic, i.e., produced not by living creatures, but manufactured by human beings. However, the feedstocks from which the chemicals are made come from nature. Commonly synthetic organic chemicals are made from crude oil or natural gas feedstocks, which are referred to as petrochemicals. Coal or wood also sometimes serves as feedstocks for organic chemicals. Plastics are synthetic organic chemicals, and the so-called bioplastics, which humans produce from plant materials, involve some synthetic chemistry. Some commercial organic chemicals are produced too by cultures of molds or bacteria; such chemicals must then be purified from these cultures by human actions.

Finally, for clarification, a biochemical is an organic chemical synthesized by a living creature. Proteins, fats, and carbohydrates are biochemicals. Sucrose (table sugar) and the acetic acid ($\text{CH}_3\text{CO}_2\text{H}$) in vinegar are examples of simple biochemicals. Many biochemicals can also be made synthetically, not only simple chemicals such as vinegar or the sugars, sucrose, and xylose, but also complex ones. If the structure of a chemical made by synthetic means is exactly the same as that found in nature, it is indeed the same chemical – the body treats both in exactly the same way, so there is no biological difference between them. Chemicals synthesized by living creatures can also be extensively manipulated during extraction and purification and still legally be called natural.

Organic Chemical Transformation Reactions

Reactions are chemical reactions involving compounds, and the basic chemical reaction types are (i) addition reactions, (ii) elimination reactions, (iii) substitution reactions, (iv) organic redox reactions, and (v) rearrangement reactions. In synthesis, reactions are used in the construction of new molecules, but in the discipline known as environmental chemistry, these reactions often occur and cause the chemical transformation of a pollutant in the environment. Factors governing reactions (hence, transformations) in the environment are essentially the same as that of any chemical reaction, and these are factors that determine the stability of reactants and products.

Furthermore, while organic reactions can be organized into several basic reaction types, some reactions fit into more than one category. Reactions can also be categorized on the basis of the type of functional group involved in the reaction as a reactant and the functional group that is formed as a result of this reaction. A functional group confers specific reactivity patterns on the molecules of which it is a part. Although the properties of each of the several million molecules whose structure is known are unique in some way, all molecules that contain the same functional group have a similar pattern of reactivity at the functional group site. Thus, functional groups are a key organizing feature of chemistry. By focusing on the functional groups present in a molecule (most molecules have more than one functional group), several of the reactions that the molecule will undergo can be predicted and understood. Thus, functional group transformation/interconversion is the process of converting one functional group into another functional group by any one (or more) of several reactions such as (i) substitution, (ii) addition, (iii) elimination, (iv) reduction, or (v) oxidation by the use of reagents under different reaction conditions.

In fact, there is no limit to the number of possible reactions and mechanisms. However, certain general patterns are observed that can be used to describe many common or useful reactions. Each reaction typically has a stepwise reaction mechanism that can be used to explain or visualize the mean by which the reaction occurs, although a detailed description of steps may not always be evident from a list of reactants alone.

Organic Chemical Transformation Reactions – Addition and Elimination Reactions

An addition reaction is an organic reaction where two or more molecules combine to form a product (the adduct) (March, 1992; Morrison *et al.*, 1992). Addition reactions are limited to chemical compounds that have multiple bonds, such as molecules with carbon-carbon double bonds (alkenes, $>C=C<$), or with triple bonds (alkynes, $-C\equiv C-$). Molecules containing carbon-heteroatom double bonds such as the carbonyl group ($>C=O$) groups, or the imine group ($C=N$) groups, can also participate in addition since they also have double bond character. An addition reaction is the reverse of an elimination reaction, such as the hydration of an alkene to an alcohol which is reversed by dehydration:

The main driver behind addition reactions to alkene is that alkenes contain the unsaturated $>C=C<$ functional group which characteristically undergoes addition reactions which is the conversion of the weaker π bond into two new, stronger σ bonds. In addition to addition reactions being typical of the unsaturated hydrocarbon derivatives (alkenes and alkynes) and aldehydes and ketones, which have a carbon-to-oxygen double bond. An addition reaction may be visualized as a process by which the double or triple bonds are fully or partially broken in order to accommodate additional atoms or groups of atoms in the molecule. Addition reactions to alkenes and alkynes are sometimes called saturation reactions because the reaction causes the carbon atoms to become saturated with the maximum number of attached groups.

In addition, reactions to aldehydes and ketones, the sequence of events is reversed insofar as the initial step is addition of the negatively charged component of the reagent to the carbon atom, followed by addition of the positively charged component to the oxygen atom.

Organic Chemical Transformation Reactions – Hydrolysis Reactions

Many compounds can be altered by a direct reaction of the chemical with water (hydrolysis) in which a chemical bond is cleaved and two new bonds are formed, each one having either the hydrogen component (H) or the hydroxyl component (OH) of the water molecule. Typically, the hydroxyl replaces another chemical group on the molecule and hydrolysis reactions are usually catalyzed by hydrogen ions or hydroxyl ions. This produces the strong dependence on the acidity or alkalinity (pH) of the solution often observed but, in some cases, hydrolysis can occur in a neutral (pH = 7) environment. Adsorption on to a mineral sediment (such as a clay sediment that has strong adsorptive powers) generally reduces the rates of hydrolysis for acid- or base-catalyzed reactions. Neutral reactions appear to be unaffected by adsorption, although there is always the possibility that the mineral sediment can cause catalyzed chemical transformation reactions.

The rate of a hydrolysis reaction is typically expressed in terms of the acid-catalyzed, neutral-catalyzed, and base-catalyzed hydrolysis rate constants. Furthermore, the hydrolysis of compounds is influenced by the composition of the solvent and the rate constants may be much higher in water than in solvents. In fact, the introduction of a complex mixture of chemicals into a water body can be expected to produce a significant shift in acidity or alkalinity of the medium and, therefore, it would not be surprising to anticipate that hydrolysis would be affected in complex mixtures.

Organic Chemical Transformation Reactions – Photolysis Reactions

Photolysis is a chemical process by which chemical bonds are broken as the result of transfer of light energy (direct photolysis) or radiant energy (indirect photolysis) to these bonds. The rate of photolysis depends upon numerous chemical and environmental factors including the light adsorption properties and reactivity of the chemical, and the intensity of solar radiation.

In the process, the photochemical mechanism of photolysis is divided into three stages: (i) the adsorption of light which excites electrons in the molecule, (ii) the primary photochemical processes which transform or de-excite the excited molecule, and (iii) the secondary thermal reactions which transform the intermediates produced in the previous step.

In addition, before photolysis can occur, the photochemically-excited state must be deactivated, such as a radiative process (fluorescence) in which energy (usually in the form of light) is emitted during the transition to ground electronic state and some residual vibrational excitation is rapidly lost via collision processes. Quenching of a photochemical process occurs when the excitation energy in the target molecule is transferred to some other chemical species in solution. This process results in net deactivation of the substance of concern via energy transfer.

Indirect photolysis or sensitized photolysis occurs when the light energy captured (absorbed) by one molecule is transferred to the molecule of concern. The donor species (the sensitizer) undergoes no net reaction in the process but has an essentially catalytic effect. Moreover, the probability of a sensitized molecule donating its energy to an acceptor molecule is proportional to the concentration of both chemical species. Thus, complex mixtures may, in some cases, produce enhancement of photolysis rates of individual constituents through sensitized reactions.

Organic Chemical Transformation Reactions – Rearrangement Reactions

Reactions typically yield products that are in accordance with the generally-accepted mechanism of the reactions. However, in some instances, reactions do not give exclusively and solely the anticipated products but may lead to other product that arises from unexpected and mechanistically different reaction path. This unexpected product is often referred to as a rearranged product and, while such a product may not be the expected product, it may be the major product of the reaction. Thus, the reaction has involved a rearrangement of the expected product to an unexpected product – a rearrangement reaction has occurred. More than likely, this may have resulted from a plausible rearrangement occurring during the mechanistic course of the reaction to fulfill the principle of the minimum energy state of the whole system, that is, of the transition state which assumed another configuration to maintain a minimum energy balance to the system. In many cases, the rearrangement affords products of an isomerization, coupled with some stereochemical changes. An energetic requirement is also observed in order for a rearrangement to take place; that is, the rearrangement usually involves an evolution of energy (typically in the form of heat, i.e., the reaction is overall an exothermic reaction) to be able to yield a more stable compound (Moulay, 2002).

Thus, a rearrangement reaction falls into a class of reactions where the carbon skeleton of an molecule is rearranged to form a structural isomer of the original molecule that assumes the minimal energy content of the product – i.e., the most stable product is formed (March, 1992; Morrison *et al.*, 1992; Moulay, 2002). As a result of the reaction, a substituent group typically moves from one atom to another atom in the same molecule to yield an isomer of the original reactant:

In the above equation, there has been movement of the substituents group (represented by R) from carbon atom number 1 to carbon atom number 2.

Thus, a rearrangement reaction is a reaction in which an atom or a group (or in some cases a bond) is caused to move or migrate to another part of the molecule. The reaction may involve several steps, but the defining feature is that the atom or a group or the bond shifts from one site of attachment to another site. The simplest (perhaps, the

most common) types of rearrangement reactions are intramolecular rearrangements insofar as the reactions occur in within one reactant molecule and the product of the reaction is a structural isomer of the reactant (Moulay, 2002).

Organic Chemical Transformation Reactions – Redox Reactions

Redox reactions (reduction-oxidation reactions) are reactions in which one chemical undergoes reduction and another chemical undergoes oxidation. Therefore, the oxidation state of the species involved must change. The word *reduction* originally referred to the loss in weight upon heating a metallic ore such as a metal oxide to extract the metal – the ore was *reduced* to the metal. However, the meaning of *reduction* has become generalized to include all processes involving gain of electrons. The term *hydrogenation* could be used instead of *reduction*, since hydrogen is the reducing agent in a large number of reactions, especially in chemistry and biochemistry. But, unlike oxidation, hydrogenation has maintained its specific connection to reactions that *add* hydrogen to another substance such as the hydrogenation processes used in a crude oil refinery. On the other hand, the word *oxidation* originally implied reaction with oxygen to form an oxide but the word has been expanded to encompass oxygen-like substances that accomplished parallel chemical reactions and ultimately, the meaning was generalized to include all processes involving loss of electrons. For example, the production of iron from the iron oxide ore:

Similarly, in the context of chemistry, there is the oxidation of ethyl alcohol ($\text{CH}_3\text{CH}_2\text{OH}$) to acetaldehyde (CH_3CHO) and the reverse reaction in which acetaldehyde is reduces to ethyl alcohol:

This equation can be sub-divided as follows into oxidation by loss of hydrogen and reduction by gain of hydrogen. Thus:

The two species that exchange electrons in a redox reaction are given special names. The ion or molecule that accepts electrons is the **oxidizing agent** which, by accepting electrons, causes the oxidation of another species. Conversely, the species that donates electrons is the **reducing agent** which, when the reaction occurs, reduces the other species. Thus, the species that is oxidized is the reducing agent and the species that is reduced is the oxidizing agent. To complicate matters even further, the oxidizing and reducing agents can be the same element or compound, as is the case when disproportionation of the reactive species occurs. For example:

In this equation, n is the number of electrons transferred. Disproportionation reactions do not need to commence with a neutral molecule and can involve more than two species with differing oxidation states.

Redox reactions are important for a number of applications, including energy storage devices (batteries), photographic processing, and energy production and utilization in living systems including humans. For example, a *reduction reaction* is a reaction in which an atom gains an electron and therefore decreases (or reduces its oxidation

number). The result is that the positive character of the species is reduced. On the other hand, an oxidation reaction is a reaction in which an atom loses an electron and therefore increases its oxidation number. The result is that the positive character of the species is increased.

Although oxidation reactions are commonly associated with the formation of oxides from oxygen molecules, these are only specific examples of a more general concept of reactions involving electron transfer. Redox reactions are a matched set, that is, there cannot be an oxidation reaction without a reduction reaction happening simultaneously. The oxidation reaction and the reduction reaction always occur together to form a whole reaction. Although oxidation and reduction properly refer to a *change in the oxidation state*, the actual transfer of electrons may never occur. The oxidation state of an atom is the fictitious charge that an atom would have if all bonds between atoms of different elements were 100% ionic. Thus, oxidation is best defined as an *increase in oxidation state*, and reduction as a *decrease in oxidation state*. In practice, the transfer of electrons will always cause a change in oxidation state, but there are many reactions that are classed as redox reactions even though no electron transfer occurs (such as those involving covalent bonds). There are simple redox processes, such as the oxidation of carbon to carbon dioxide (CO₂) or the reduction of carbon by hydrogen to methane (CH₄).

The key to identifying oxidation-reduction reactions is recognizing when a chemical reaction leads to a change in the oxidation number of one or more atoms.

Organic Chemical Transformation Reactions – Substitution Reactions

A substitution reaction (sometimes referred to as a single displacement reaction or single replacement reaction) is a reaction in which a functional group in an organic chemical is replaced by another functional group (March, 1992; Morrison *et al.*, 1992). Substitution reactions are of prime importance in environmental organic chemistry because of the simplicity of the reaction which is accompanied by a substantial change in the chemical and physical properties of the product vis-à-vis compared to the chemical and physical properties of the starting chemical. Substitution reactions in organic chemistry are classified either as (i) nucleophilic substitution or (ii) electrophilic substitution depending upon the reagent involved.

A nucleophile is a chemical species (an ion or a molecule) which is strongly attracted to a region of positive charge in something else. Nucleophiles are either fully negative ions, or else have a strongly (δ-) charge somewhere on a molecule. Common nucleophiles are hydroxide ions (OH⁻), cyanide ions (CN⁻), water (H₂O), and ammonia (NH₃). An example of a simple nucleophilic substitution reaction is the halogenation of an alkane such as when methane (CH₄) is reacted with chlorine (Cl₂) to form methyl chloride and hydrogen chloride:

Thus, a nucleophilic substitution reaction (which is common in organic chemistry) is a reaction in which an electron-rich nucleophile selectively bonds with or attacks the positive or partially positive charge of an atom or a group of atoms to replace the leaving electrophile:

On the other hand, electrophilic substitution involves electrophiles, and an example is electrophilic aromatic substitution. In this type of substitution, the benzene ring (which has a π-electron cloud above and below the plane of the ring of carbon atoms) is attacked by an electrophile (shown as E⁺). The π-electron cloud is disturbed, and a carbocation resonating structure results after which a proton (H⁺) is ejected from the intermediate and a new aromatic compound is formed:

A relevant reaction in the environment (because of the ever-presence of water in many ecosystems) is the hydrolysis reaction in which a chemical compound is decomposed by reaction with water – also, the hydrolysis reaction should not be confused with the *hydrogenolysis* reaction which is a reaction of hydrogen as practiced widely in the crude oil industry to produce liquid fuels. Hydrolysis is an example of a larger class of reactions referred to as nucleophilic displacement reactions in which a nucleophile (an electron-rich species containing an unshared pair of electrons) attacks an electrophilic atom (an electron-deficient reaction center). Hydrolytic processes encompass several types of reaction mechanisms that can be defined by the type of reaction center (i.e., the atom bearing the leaving group, X) where hydrolysis occurs. The reaction mechanisms encountered most often are direct and indirect nucleophilic substitution and nucleophilic addition-elimination.

This type of reaction can be used to predict the persistency of a chemical in the environment, the physical-chemical properties of the chemical, and the reactivity of the chemical in the environment need to be known or at least estimated (Rahm *et al.*, 2005). The chemicals that can undergo elimination reactions are rapidly transformed, as are perhalogenated chemicals that can undergo substitution reactions. These chemicals are not likely to persist in the environment, while those that do not show any observable reactivity under similar hydrolytic conditions are likely to be persistent pollutants (POPs) and the fate of these chemicals is linked to the cycling of chemicals in the environment.

Typically, the hydrolysis reaction is a chemical transformation in which a molecule, RX, reacts with water, resulting in the formation of a new covalent bond with the hydroxy function (OH) and cleavage of the covalent bond with halogen function (e.g., Cl) (the leaving group) in the original molecule. The net reaction is the displacement of the halogen group (X) by the hydroxyl group (OH). In fact, for many types of contaminants, hydrolysis may be the dominant pathway for their transformation in aquatic ecosystems. Hydrolytic processes are not limited to the bodies of water such as rivers, streams, lakes, and oceans usually associated with the term aquatic ecosystems. Hydrolysis of chemicals can also occur in groundwater systems and the aqueous environment in solids and sediments.

In the aqueous hydrolysis reaction, the reacting water molecules are split into hydrogen (H^+) and hydroxide (OH^-) ions, which react with and break up the other reacting compound. The term *hydrolysis* is also applied to the electrolysis of water (that is, breaking up of water molecules by an electric current) to produce hydrogen and oxygen. The hydrolysis reaction is distinct from a *hydration reaction*, in which water molecules attach to molecules of the other reacting compound without breaking up the latter compound, such as:

The hydrolysis reaction mainly occurs between an ion and water molecules and often changes the pH (acidity or alkalinity) of a solution. In chemistry, there are three main types of hydrolysis (i) salt hydrolysis, (ii) acid hydrolysis, and (iii) base hydrolysis.

In water, salts will dissociate to form ions (either completely or incompletely depending on the respective solubility constant, K_{sp}). For example:

In this equation, the salt (ammonium bromide, NH_4Br) is dissolved in water upon which the salt dissociates into ammonium ions (NH_4^+) and bromide ions (Br^-).

In the hydrolysis reaction, water can act as an acid or a base: (i) if that water acts as an acid, the water molecule would donate a proton (H^+), also written as a hydronium ion (H_3O^+) or (ii) if the water acts as a base, the water molecule would accept a proton (H^+). An acid hydrolysis reaction is very much the same as an acid dissociation reaction.

In the above reaction, the proton H^+ from CH_3COOH (acetic acid) is donated to water, producing the hydronium ion (H_3O^+) and an acetate ion (CH_3COO^-). The bonds between proton and the acetate ion are dissociated by the addition of water molecules. A reaction with acetic acid (CH_3COOH), a weak acid, is similar to an acid-dissociation reaction, and water forms a conjugate base and a hydronium ion. When a weak acid is hydrolyzed, a hydronium ion is produced.

A base hydrolysis reaction will resemble the reaction for base dissociation. A common weak base that dissociates in water is ammonia:

In the hydrolysis of ammonia, the ammonia molecule accepts a proton from the water (i.e., water acts as an acid), producing a hydroxide anion (OH^-). Similar to a basic dissociation reaction, ammonia forms ammonium and a hydroxide from the addition of a water molecule.

Generally, in chemistry, hydrolysis can be considered the reverse (or opposite) of condensation, a reaction in which two molecular fragments are joined for each water molecule produced. Since hydrolysis may be a reversible reaction, condensation and hydrolysis can take place at the same time, with the position of equilibrium determining the amount of each product, such as the hydrolysis of an ester to an acid and an alcohol:

Thus, hydrolysis reactions involving compounds may be illustrated by the reaction of water with an ester of a carboxylic acid; all such esters have the general formula R^1COOR^2 , in which R^1 and R^2 are combining groups (for example, if R^1 and R^2 are both methyl groups, CH_3 , the ester is methyl acetate). The hydrolysis involves several steps, of which the slowest is the formation of a covalent bond between the oxygen atom of the water molecule and the carbon atom of the ester. In succeeding steps, which are very rapid, the carbon-oxygen bond of the ester breaks and hydrogen ions become detached from the original water molecule and attached to the nascent alcohol molecule. The whole reaction is represented by the equation:

Thus, the products of hydrolysis depend very much upon that substrate that is to be hydrolyzed.

More pertinent to the present text, the hydrolysis of a pesticide is basically a reaction with a water molecule involving specific catalysis by proton or hydroxide, and sometimes in ions such as phosphate ion, present in the aquatic environment that play a role in general acid-base catalysis (Katagi, 2002). However, the hydrolytic profiles depend on the chemical structure and functional group(s) in the pesticide molecule, which are not always consistent within a chemical class of pesticides (Stoytcheva, 2011). For example, pesticides that are composed of organophosphorus derivatives are primarily susceptible to alkaline hydrolysis with less acidic catalysis, but some of phosphorodithioate derivatives are found to be acid labile. Various instrumental techniques have been applied to chemical identification of degraded products, leading to clarification of the reaction mechanisms involved. Moreover, pesticides are usually applied as a suitable formulation, and thus the effects of surfactants and other formulation reagents on hydrolysis should be examined in more detail. To assess the fate and impact of pesticides and their degraded products in real aquatic environments, these concerns should be further examined using the various analytical techniques together with simulation models.

When substituted benzene compounds undergo electrophilic substitution reactions, it is necessary to compare the relative reactivity of the compound compared with benzene itself. Experiments have shown that substituents on a benzene ring can influence reactivity in a profound manner. For example, a hydroxy substituent ($-OH$) or methoxy ($-OCH_3$) substituent increases the rate of electrophilic substitution approximately ten thousand-fold. In contrast, a nitro substituent decreases the reactivity of the ring substantially. This **activation or deactivation** of the benzene

ring toward electrophilic substitution may be correlated with the electron-donating or electron-withdrawing influence of the substituents, as measured by molecular dipole moments. Electron-donating substituents activate the benzene ring toward electrophilic attack, and electron-withdrawing substituents deactivate the benzene ring and render it less reactive to electrophilic attack.

The influence a substituent exerts on the reactivity of a benzene ring may be explained by the interaction of two effects: (i) an inductive effect, and (ii) a conjugative effect. The *inductive effect* arises because most elements other than metals and carbon have a significantly greater electronegativity than hydrogen. Consequently, substituents in which nitrogen, oxygen, and halogen atoms form sigma-bonds to the aromatic ring exert an inductive electron withdrawal, which deactivates the ring (left-hand diagram below). The second effect (the conjugative effect) is the result of a conjugation of a substituent function with the aromatic ring which facilitates electron pair donation or withdrawal, to or from the benzene ring, in a manner different from the inductive shift. If the atom bonded to the ring has one or more non-bonding valence shell electron pairs, as do nitrogen, oxygen, and the halogens, electrons may flow into the aromatic ring by π conjugation (resonance), as in the middle diagram. Finally, polar double and triple bonds conjugated with the benzene ring may withdraw electrons, as in the right-hand diagram. The charge distribution in the benzene ring is greatest at sites ortho and para to the substituent. In the case of the nitrogen- and oxygen-activating groups displayed in the top row of the previous diagram, electron donation by resonance dominates the inductive effect and these compounds show exceptional reactivity in electrophilic substitution reactions. Although halogen atoms have non-bonding valence electron pairs that participate in p - π conjugation, their strong inductive effect predominates, and compounds such as chlorobenzene are less reactive than benzene.

Organic Matter

The organic material of soil, called humus, is made up of microorganisms (dead and alive), and dead animals and plants in varying stages of decay. Humus improves soil structure, providing plants with water and minerals

The solid fraction of typical productive soil is ca. 5% w/w organic matter and ca. 95% w/w inorganic matter. Some soils, such as peat soils, may contain as much as 95 % organic material. Other soils contain as little as 1% w/w organic matter. Though typically comprising less than 5% w/w of a productive soil, organic matter in soil largely determines soil productivity. It serves as a source of food for microorganisms, undergoes chemical reactions such as ion exchange, and influences the physical properties of soil. Some organic compounds even contribute to the weathering of mineral matter, the process by which soil is formed.

Humus is a generic term for the water-insoluble material that makes up the bulk of soil organic matter (Stevenson, 1994). Humus is composed of a base-soluble fraction (humic and fulvic acids) and an insoluble fraction (humin) and is the residue from the biodegradation (by bacteria and fungi) of plant material. The bulk of plant biomass consists of relatively degradable cellulose and degradation-resistant lignin, a complex polymeric substance that is second only to carbohydrates in natural abundance. Lignin is a precursor of soil humus.

The accumulation of organic matter in soil is strongly influenced by temperature and by the availability of oxygen. Since the rate of biodegradation decreases with decreasing temperature, organic matter does not degrade rapidly in

colder climates and tends to build up in soil. In water and in waterlogged soils, decaying vegetation does not have easy access to oxygen, and organic matter accumulates. The organic content may reach 90% w/w in areas where plants grow and decay in soil saturated with water. Of the organic components, humus is by far the most significant.

An increase in the atomic nitrogen/carbon ratio is a significant feature of the transformation of plant biomass to humus. During the humification process, microorganisms convert organic carbon to carbon dioxide to obtain energy. Simultaneously, the bacterial action incorporates bound nitrogen with the compounds produced by the decay processes. The result is a nitrogen/carbon ratio of ca. 1/10 upon completion of humification. As a general rule, therefore, humus is relatively rich in organically bound nitrogen.

Humic materials in soil strongly adsorb many solutes in soil water and have a particular affinity for heavy polyvalent cations. Soil humic substances may contain levels of uranium more than 10,000 times that of the water with which they are in equilibrium. Thus, water becomes depleted of its cations (or purified) in passing through humic-rich soils. Humic substances in soils also have a strong affinity for organic compounds with low water solubility such as the types of herbicides widely used to kill weeds.

In some cases, there is a strong interaction between the organic and inorganic portions of soil. This is especially true of the strong complexes formed between clay minerals and humic (fulvic) acid compounds. In many soils, 50-100% of the soil carbon is in the form of complexes with clay. These complexes play a role in determining the physical properties of soil, soil fertility, and stabilization of soil organic matter. One of the mechanisms for the chemical binding between clay colloidal particles and humic organic particles are probably of the flocculation type, in which anionic organic molecules with carboxylic amid functional groups serve as bridges in combination with cations to bind clay colloidal particles together as a floe.

The synthesis, chemical reactions, and biodegradation of humic materials are affected by interaction with clay minerals. The lower-molecular-weight fulvic acids may be bound in the spaces in layers in clay particles.

Organic Solvents

Solvents are liquids or gases that can dissolve or extract other substances and are an essential part of laboratory operations – typically for use to dissolve substances or for cleaning – and must be used with caution. Solvents are used to dissolve materials such as grease, oil, and paint, to thin or mix pigments, paint, glue, and pesticides.

The term *solvents* usually refers to organic solvents, which contain carbon and can be classified into three main types: (i) hydrocarbon solvents, (ii) oxygenated solvents, and (iii) halogenated solvents. Hydrocarbon solvents contain hydrogen and are derived mainly from petroleum, while oxygenated solvents are synthesized from other chemicals. Halogenated solvents contain one or more of the halogen elements: chlorine, bromine, fluorine, or iodine.

In the interests of safety and health, the properties of any solvent must be determined before use.

Other Energy Resources

It is predictable that fossil fuels will be the primary source of energy for the next several decades, well into the next century, and therefore the message is clear: until other energy sources supplant coal, natural gas, and crude oil, the challenge is for the development of technological concepts that will provide the maximum recovery of energy from these fossil fuel resources. Thus, it is absolutely essential that energy from such resources be obtained not only cheaply but also efficiently and with minimal detriment to the environment.

To complete the energy resource scenario and to put the fossil energy resources into perspective, there are non-fossil fuel energy resources which are derived from the sun and are generically referred to as non-fossil resources, or renewable resources, or/and geophysical energy resources. And even though it is not widely recognized, since renewable energy resources are assumed to be “natural” and therefore in harmony with nature, there are environmental issues that need to be addressed when renewable energy resources are to be employed.

Beyond this, there is much doubt related to the time when humans can look forward to the generation of energy from the unconventional sources. The time scale for the generation of electrical energy from such sources is generally

unknown or, at best, open to much speculation and criticism. The resources include direct solar energy, hydroelectric energy, wind energy, geothermal energy, energy from biomass, and elements of minerals from which nuclear energy may be derived.

Nuclear energy, which can be as hazardous as any fossil fuel in terms of destruction of the environment, deserves some comment insofar as an appreciation of its use may assist in the general background and aid in putting fossil fuel resources into a more complete context. Energy from nuclear sources has shown potential to be a significant energy source in the future.

Energy from nuclear sources may be the result of nuclear fission, which uses uranium ore or refined uranium-235 as its basic energy source. The ore must be concentrated into fissionable isotopes through nuclear processing. Eventually, the spent material must be replaced, hence the need to explore the potential for generating more of the fissionable isotopes. However, the use of such materials has become the core of a major controversy which threatens to be, at least for the time being, the death-knell of the nuclear industry.

Nuclear fusion, unlike nuclear fission which involves the use of fissionable material, involves the fusion of hydrogen nuclei. The concept has been suggested as having the potential to provide a clean and virtually unlimited supply of energy.

Oxidation

Oxidation is a process which can be used for the treatment of a variety of inorganic and organic substances.

The oxidation of hydrocarbon derivatives and hydrocarbon mixtures has received considerable attention, but the uncontrollable nature of the reaction and the mixed character of the products have made resolution of the reaction sequences extremely difficult.

Therefore it is not surprising that, except for the preparation of mixed products having specific properties, such as fatty acids, hydrocarbon derivatives higher than pentanes are not employed for oxidation because of the difficulty of isolating individual compounds.

Methane undergoes two useful reactions at 90°C (195°F) in the presence of iron oxide (Fe_3O_4) as a catalyst:

Alternatively, partial combustion of methane can be used to provide the required heat and steam. The carbon dioxide produced then reacts with methane at 900°C (1,650°F) in the presence of a nickel catalyst:

Methanol (methyl alcohol, CH_3OH) is the second major product produced from methane. Synthetic methanol has virtually completely replaced methanol obtained from the distillation of wood, its original source material. One of the older trivial names used for methanol was wood alcohol. The synthesis reaction takes place at 350°C (650°F) and 4,400 psi in the presence of ZnO as a catalyst:

Most of the methanol is then oxidized by oxygen from air to formaldehyde (sometimes referred to as *methanal*):

Formaldehyde is used to produce synthetic resins either alone or with phenol, urea, or melamine; other uses are minor.

By analogy to the reaction with oxygen, methane reacts with sulfur in the presence of a catalyst to give the carbon disulfide used in the rayon industry:

When propane and butane are oxidized in the vapor phase, without a catalyst, at 270 to 350°C (520 to 660°F) and at 50 to 3,000 psi, a wide variety of products is obtained, including C₁ to C₄ acids, C₂ to C₇ ketones, ethylene oxide, esters, formals, acetals, and others.

Cyclohexane is oxidized commercially and is somewhat selective in its reaction with air at 150 to 250°C (300 to 480°F) in the liquid phase in the presence of a catalyst, such as cobalt acetate. Cyclohexanol derivatives are the initial products, but prolonged oxidation produces adipic acid. On the other hand, oxidation of cyclohexane and methylcyclohexane over vanadium pentoxide at 450 to 500°C (840 to 930°F) affords maleic and glutaric acids.

The preparation of carboxylic acids from crude oil, particularly from paraffin wax, for esterification to fats or neutralization to form soaps has been the subject of a large number of investigations. Wax oxidation with air is comparatively slow at low temperature and normal pressure, little reaction taking place at 110°C (230°F), with a wax melting at 55°C (130°F) after 280 h. At higher temperatures, the oxidation proceeds more readily; maximum yields of mixed alcohol and high-molecular-weight acids are formed at 110 to 140°C (230 to 285°F) at 60 to 150 psi; higher temperatures (140 to 160°C, 285 to 320°F) result in more acid formation:

Acids from formic (HCO₂H) to that with a 10-carbon atom chain [CH₃(CH₂)₉CO₂H] have been identified as products of the oxidation of paraffin wax. Substantial quantities of water-insoluble acids are also produced by the oxidation of paraffin wax, but apart from determination of the average molecular weight (ca. 250), little has been done to identify individual numbers of the product mixture.

By analogy to the reaction with oxygen, methane reacts with sulfur in the presence of a catalyst to give the carbon disulfide used in the rayon industry:

The major non-petrochemical use of methane is in the production of hydrogen for use in the Haber synthesis of ammonia. Ammonia synthesis requires nitrogen, obtained from air, and hydrogen. The most common modern source of the hydrogen consumed in ammonia production, approximately 95% of it, is methane.

Oxygen

Oxygen occurs in both the organic and inorganic portions of coal. In the organic portion, oxygen is present in hydroxyl (-OH), usually phenol groups, carboxyl groups (CO₂H), methoxyl groups (-OCH₃), and carbonyl groups (=C=O). In low-rank coal, the hydroxyl oxygen averages approximately 6 to 9%, while high-rank coals contain less than 1%. The percentages of oxygen in carbonyl, methoxyl, and carboxyl groups average from a few percent in low rank and brown coal to almost no measurable value in high-rank coal. The inorganic materials in coal that contain oxygen are the various forms of moisture, silicates, carbonates, oxides, and sulfates. The silicates are primarily aluminum silicates found in the shale-like portions. Most of the carbonate is calcium carbonate (CaCO₃), the oxides are mainly iron oxides (FeO and Fe₂O₃), and the sulfates are calcium and iron (CaSO₄ and FeSO₄).

Oxygenated Gasoline

Oxygenated gasoline is gasoline with added ethers or alcohols, formulated according to the Federal Clean Air Act to reduce carbon monoxide emissions during winter months.

See also: Oxygenates

Oxygenates

Oxygenates are chemical compounds which, when added to gasoline, increase the amount of oxygen in that gasoline blend; include fuel ethanol, methanol, and methyl-tertiary-butyl ether (MTBE).

Oxygenates are carbon-, hydrogen-, and oxygen-containing combustible liquids that are added to gasoline to improve performance. The addition of oxygenates gasoline is not new since ethanol (ethyl alcohol or grain alcohol) has been added to gasoline for decades. Thus, *oxygenated gasoline* is a mixture of conventional hydrocarbon-based gasoline and one or more oxygenates. The current oxygenates belong to one of two classes of organic molecules: alcohols and ethers. The most widely used oxygenates in the United States are ethanol, methyl tertiary-butyl ether (MTBE), and tertiary-amyl methyl ether (TAME). Ethyl tertiary-butyl ether (ETBE) is ether that could be used. Oxygenates may be used in areas of the United States where they are not required as long as concentration limits (as defined by environmental regulations) are observed.

Of all the oxygenates, methyl-t-butyl ether (MTBE) is attractive for a variety of technical reasons. It has a low vapor pressure, can be blended with other fuels without phase separation, and has the desirable octane characteristics. If oxygenates achieve recognition as vehicle fuels, the biggest contributor will probably be methanol, the production of which is mostly from synthesis gas derived from methane.

The higher alcohols also offer some potential as motor fuels. These alcohols can be produced at temperatures below 300°C (570°F) using copper oxide-zinc oxide-alumina catalysts promoted with potassium. Iso-butyl alcohol is of particular interest because of its high octane rating, which makes it desirable as a gasoline-blending agent. This alcohol can be reacted with methanol in the presence of a catalyst to produce methyl-t-butyl ether. Although it is currently cheaper to make iso-butyl alcohol from iso-butylene, it can be synthesized from syngas with alkali-promoted zinc oxide catalysts at temperatures above 400°C (750°F).

Oxygen Compounds

Oxygen in organic compounds – especially organic compounds that are produced from the various types of biomass, such as bio-oil – can occur in a variety of forms (ROH , ArOH , R^1OR^2 , RCO_2H , ArCO_2H , RCO_2R , ArCO_2R , $\text{R}_2\text{C}=\text{O}$ as well as the cyclic furan derivatives, where R, R^1 , and R^2 are alkyl groups and Ar is an aromatic group) in nature, so it is not surprising that the more common oxygen-containing compounds occur in crude oil. The total oxygen content of crude oil is usually less than 2% w/w, although larger amounts have been reported, but when the oxygen content is phenomenally high, it may be that the oil has suffered prolonged exposure to the atmosphere either during or after production. However, the oxygen content of crude oil increases with the boiling point of the fractions examined; in fact, the nonvolatile residua may have oxygen contents up to 8% w/w. Although these high-molecular-weight compounds contain most of the oxygen in crude oil, little is known concerning their structure, but those of lower molecular weight have been investigated with considerably more success and have been shown to contain carboxylic acids and phenols.

The presence of acid substances in crude oil first appears to have been reported in 1874, and it was established 9 years later that these substances contained carboxyl groups and were carboxylic acids. These were termed naphthenic acids. Although alicyclic (naphthenic) acids appear to be the more prevalent, it is now well known that aliphatic acids are also present. In addition to the carboxylic acids, alkaline extracts from crude oil contain phenols.

It has generally been concluded that the carboxylic acids in crude oil with fewer than eight carbon atoms per molecule are almost entirely aliphatic in nature; monocyclic acids begin at C_6 and predominate above C_{14} . This indicates that the structures of the carboxylic acids correspond with those of the hydrocarbon derivatives with which they are associated in the crude oil. In the range in which paraffins are the prevailing type of hydrocarbon, the aliphatic acids may be expected to predominate. Similarly, in the ranges in which monocycloparaffin derivatives and dicycloparaffin derivatives prevail, one may expect to find principally monocyclic and dicyclic acids, respectively.

In addition to the carboxylic acids and phenolic compounds, the presence of ketones, esters, ethers, and anhydrides has been claimed for a variety of crude oils. However, the precise identification of these compounds is difficult because most of them occur in the higher-molecular-weight nonvolatile residua. They are claimed to be products of the air blowing of the residua, and their existence in virgin crude oil may yet need to be substantiated.

Although comparisons are frequently made between the sulfur and nitrogen contents and such physical properties as the API gravity, it is not the same with the oxygen contents of crude oils. It is possible to postulate, and show, that such relationships exist. However, the ease with which some of the crude oil constituents can react with oxygen (aerial or dissolved) to incorporate oxygen functions into their molecular structure often renders the exercise somewhat futile if meaningful deductions are to be made.

Oxygen Cycle

The oxygen cycle is the biogeochemical transitions of oxygen atoms between different oxidation states in ions, oxides, and molecules through redox reactions within and between the spheres and reservoirs of the planet Earth. The word redox typically refers to the most common oxygen allotrope, elemental/diatomic oxygen (O_2), as it is a common product or reactant of many biogeochemical redox reactions within the cycle. Processes within the oxygen cycle are considered to be biological or geological and are evaluated as either a source (oxygen production) or a sink (oxygen consumption).

In the oxygen cycle, the circulation of oxygen in various forms occurs in nature. Free in the air and dissolved in water, oxygen is second only to nitrogen in abundance among uncombined elements in the atmosphere. Plants and animals use oxygen to respire and return it to the air and water as carbon dioxide (CO_2) which is then taken up by algae and terrestrial green plants and converted into carbohydrates during the process of photosynthesis with oxygen being a by-product. The waters of the world are the main oxygen generators of the biosphere; their algae are estimated to replace approximately 90% of all oxygen used. Oxygen is involved to some degree in all the other biogeochemical cycles. For example, over time, detritus from living organisms transfers oxygen-containing compounds (such as calcium carbonate) into the lithosphere.

See also: Biogeochemical Cycles, Geological Cycles.

Oxygen Delignification

Oxygen delignification is primarily intended to facilitate the delignification process, i.e., bleaching. More effective delignification enables the process to reduce the use of hazardous and expensive chemicals in the bleach plant.

Oxygen delignification is a process between cooking and bleaching sequences, where part of the residual lignin left in pulp after cooking is removed using oxygen and alkali. Oxygen delignification is a direct extension to delignification in cooking. The targeted reactions are the oxidation of lignin and breaking it down to parts which dissolve in alkali, as well as destroying the colored groups in lignin and removal of impurities, such as resin.

In the process, oxygen is reduced to water in reactions with the organic components, and the organic components are oxidized. Oxygen in its normal state is a weak oxidizing agent, and is as such ineffective in delignification. Its oxidizing power can be promoted by raising the temperature and by alkaline conditions.

The most essential factor in oxygen delignification is to bring oxygen gas into contact with the fibers under alkaline conditions – the pulp suspension should have enough alkaline (hydroxyl ions) to neutralize and dissolve the organic acids, which are generated in oxygen-lignin reactions.

Oxygen delignification can be done in medium or high consistency. A high consistency oxygen stage is more expensive and more difficult to process than a medium consistency stage. Medium consistency oxygen delignification can be performed as a single- or two-stage system. The number of stages depends on the extent of the reaction required.

With the increasing importance of environmental conservation and the inevitable depletion of the fossil fuel supplies of the Earth, it is necessary to develop renewable and clean sources of energy. Bioconversion, the process of converting plant biomass to fuel-grade ethanol, is one process that addresses these concerns. However, despite promising results, the development of a more feasible pretreatment process to be used upstream of enzymatic hydrolysis is required. Oxygen delignification has long been successfully employed in the pulp and paper industry to remove the lignin from pulp samples.

Ozone

Ozone (O_3) occurs naturally in the upper layers of the atmosphere. This important gas shields the earth from the harmful ultraviolet rays of the sun. However, at the ground level, it is a pollutant with highly toxic effects. **Ozone depletion** is another result of pollution. The ozone layer in the stratosphere protects the earth from harmful *ultraviolet radiation* from the sun. Release of *chlorofluorocarbons* (CFCs) from aerosol cans, cooling systems, and refrigerator equipment remove some of the ozone, causing “holes,” to open up in this layer and allowing the radiation to reach the earth. Ozone is a powerful oxidizing agent and unstable at high concentrations, decaying to ordinary diatomic oxygen (in approximately half an hour in atmospheric conditions):

This reaction proceeds more rapidly with increase in temperature and decrease in pressure.

Ozone also increases the oxidation number of oxides, such as the oxidation of nitric oxide to nitrogen dioxide:

The NO_3 formed can react with NO_2 to form N_2O_5 :

Ozone reacts with carbon to form carbon dioxide, even at room temperature:

Ozone does react with ammonia to form ammonium nitrate:

Sulfuric acid can be produced from ozone, starting either from elemental sulfur or from sulfur dioxide:

In the gas phase, ozone reacts with hydrogen sulfide to form sulfur dioxide:

In an aqueous solution, however, two competing simultaneous reactions occur, one to produce elemental sulfur, and one to produce sulfuric acid:

Nitryl perchlorate can be made from NO_2 , ClO_2 , and O_3 gases:

See also: Oxygen, Ozone Layer

Ozone Layer

Ozone only makes up approximately 0.00006% of the atmosphere, and the highest levels of ozone in the atmosphere are in the *stratosphere*, in a region also known as the ozone layer between approximately 4 to 20 miles above the surface (or between approximately 6 and 31 miles). The ozone layer filters out photons with shorter wavelengths (less than 320 nm) of ultraviolet light (UV rays, 270 to 400 nm) from the Sun which, in large doses, would be harmful to most forms of life in large doses. These same wavelengths are also among those responsible for the production of vitamin D, a vitamin also produced by the human body.

Ozone in the stratosphere is mostly produced from ultraviolet rays reacting with oxygen:

Ozone is destroyed by the reaction with atomic oxygen:

The latter reaction is catalyzed by the presence of certain free radicals, of which the most important are hydroxyl (OH), nitric oxide (NO), atomic chlorine (Cl), and bromine (Br).

In recent decades – since the middle of the 20th century – there has been a noticeable decrease in the amount of ozone in the stratosphere mostly because of emissions of chlorofluorocarbons (CFCs) and similar chlorinated and brominated organic molecules, which have increased the concentration of ozone-depleting catalysts above the natural background.

Packed Bed

A packed bed – in the current context – is a hollow tube, pipe, or other vessel that is filled with a packing material such as a neutral non-reactive material to provide a large surface area or a catalyst. The packing can be randomly filled with small objects like Raschig rings, or else, it can be a specifically designed structured packing. Packed beds may also contain catalyst particles or adsorbents such as zeolite pellets or granular activated carbon.

The purpose of a packed bed is typically to improve contact between two phases in a chemical or similar process. Packed beds can be used in a chemical reactor, a distillation process, or a scrubber, but packed beds have also been used to store heat in chemical plants. In this case, hot gases are allowed to escape through a vessel that is packed with a refractory material until the packing is hot. Air or other cool gas is then fed back to the plant through the hot bed, thereby pre-heating the air or gas feed.

Another factor, in addition to the packing shape and surface area, is the liquid and vapor distribution that enters the packed bed. The number of theoretical stages required to make a given separation is calculated using a specific vapor-to-liquid ratio. If the liquid and vapor are not evenly distributed across the superficial tower area as it enters the packed bed, the liquid-to-vapor ratio will not be correct and the required separation will not be achieved. The packing will appear to not be working in the correct manner. Also, the packed bed columns can contain liquid distributors and redistributors which help to distribute the liquid evenly over a section of packing, increasing the efficiency of the mass transfer.^[1] The design of the liquid distributors used to introduce the feed and reflux to a packed bed is critical to making the packing perform at maximum efficiency.

See also: Packed Bed Reactor, Packed Scrubber.

Packed Bed Reactor

A packed bed reactor (also known as a fixed bed reactor) is the most commonly applied reactor in the crude oil and energy industries. In the reactor, the catalyst particles (usually in the form of pellets with the particle diameter varying from a several millimeters to several centimeters) are placed in a tube, through which the fluid is passed. Generally, the catalyst particles are immobile. Excessively small particle sizes are avoided since they start moving as the flow velocity increases. Additionally, small particles cause a drop in the pressure in the reactor. On the other hand, when using large catalyst particles, the diffusion distance to the active sites inside the catalyst increases.

In the simplest form, a catalytic reactor consists of a cylindrical tube packed with small catalyst pellets and ‘surrounded’, in the case of an exothermic reaction, by a cooling medium. Reactant gases enter the bottom of the reactor, and the reaction occurs on the surface of the catalyst. Because of the presence of the cooling medium, the temperature at the center of the reactor will be higher than that at the tube wall. As a result, the reaction rate will be much higher at the center than at the wall and accordingly, the products of the reaction will tend to accumulate at the center while the reactants are accumulating at the wall.

The design of a packed bed is influenced by the structure of the packing matrix, which in turn is governed by the shape, dimensions, and the loading of the constituent particles. For reactor applications, the optimum design of catalyst pellet in terms of shape configuration, internal pores, and available surface area can promote catalytic activity and the prevailing transport properties of the system. Also, at the design stage, resistance to crushing and abrasion, as well as dust build-up, should also be taken into account. Knowledge of the underlying factors should enable designers to design the optimum configuration for a given system with prescribed conditions.

The bed of catalyst pellets is generally considered as if it is a continuous homogeneous media, and the physical properties of the packed bed or system are assigned values on the basis of a weighted average of each of the individual constituents making up the system. The weighting procedure is, in almost all cases, determined by a macroscopic or

bulk contribution of all the components present in the system. The properties, such as (i) porosity, (ii) mass velocity, and (iii) thermal conductivity will vary smoothly throughout the packed bed and, as a consequence, the solution of the differential equations representing the heat, mass, and momentum distributions will necessarily give rise to, correspondingly, smoothly varying values of temperature, concentration, and velocity.

See also: Fixed Bed Reactor or Moving Bed Reaction, Packed Bed, Packed Bed Scrubber.

Packed-Bed Scrubber

A packed-bed scrubber consists of a bed of packing elements, such as coke, broken rock, rings, saddles, or other manufactured elements. The packing breaks down the liquid flow into a high-surface-area film so that the dusty gas streams passing through the bed achieve maximum contact with the liquid film and become deposited on the surfaces of the packing elements. This type of scrubber has a high collection efficiency for respirable dust.

The packed bed scrubber, or packed tower, is designed to remove gaseous or vaporous pollutants from an air stream. The process is accomplished by contacting the contaminated air stream with scrubbing liquor that absorbs or chemically reacts with the pollutants. Some vapors can be simply removed by condensation through the cooling effect of the circulating liquid. The cleaned air is then discharged to the atmosphere, and the contaminated scrubbing liquor is either disposed of in an approved manner or chemically treated and recycled. In some cases, the collected contaminants can be recovered and reused in the original or other processes.

In order to optimize the contaminant removal efficiency, the contact between the contaminated air and the scrubbing liquor must be maximized. To achieve this, specially designed packing materials are used to fill the tower to a specified depth. The combination of packing material, packing design, depth of packing, bed velocity, and the scrubbing liquor chemistry and amount all combine to achieve the desired results. Since every system must be looked at individually, each unit is custom tailored to meet the specific needs of the application. Therefore, system size is virtually unlimited and scrubbers of all sizes are in use.

This countercurrent vertical scrubber is most commonly used for the removal of noxious gases from gas streams. It is designed for high collection efficiencies and maximum corrosion resistance.

See also: Packed Bed, Packed Bed Reactor.

Paraffin Hydrocarbons

The proportion of paraffins in crude oil varies with the type of crude, but within any one crude oil, the proportion of paraffinic hydrocarbon derivatives usually decreases with increasing molecular weight and there is a concomitant increase in aromaticity and the relative proportion of heteroatoms (nitrogen, oxygen, and sulfur).

The relationship between the various hydrocarbon constituents of crude oils is one of hydrogen addition or hydrogen loss. This is an extremely important aspect of crude oil composition, and there is no reason to deny the occurrence of these inter-conversion schemes during the formation, maturation, and *in situ* alteration of crude oil. Indeed, a scheme of this type lends even more credence to the complexity of crude oil within the hydrocarbon series alone and also supports current contentions that the high-molecular-weight constituents (resin constituents and asphaltene constituents) are structurally related to the lower-boiling constituents rather than proposals that invoke the existence of highly condensed polynuclear aromatic systems.

The abundance of the different members of the same homologous series varies considerably in absolute and relative values. However, in any particular crude oil or crude oil fraction, there may be a small number of constituents forming the greater part of the fraction, and these have been referred to as the *predominant constituents*. This generality may also apply to other constituents and is very dependent upon the nature of the source material as well as the relative amounts of the individual source materials prevailing during maturation conditions.

Normal paraffin hydrocarbon derivatives (*n*-paraffins, straight-chain paraffins) occur in varying proportions in most crude oils. In fact, paraffinic crude oil may contain up to 20 to 50% w/w *n*-paraffins in the gas oil fraction. However, naphthenic or asphaltic crude oils sometimes contain only small amounts of normal paraffins.

Considerable quantities of *iso-paraffins* have been noted to be present in the straight-run gasoline fraction of crude oil. The 2- and 3-methyl derivatives are the most abundant, and the 4-methyl derivative is present in small amounts. If at all, it is generally accepted that the slightly branched paraffins predominate over the highly branched materials. It seems that the *iso*-paraffins occur throughout the boiling range of crude oil fractions. The proportion tends to decrease with increasing boiling point; it appears that if the *iso*-paraffins are present in lubricating oils, their amount is too small to have any significant influence on the physical properties of the lubricating oils.

As the molecular weight (or boiling point) of the crude oil fraction increases, there is a concomitant decrease in the amount of free paraffins in the fraction. In certain types of crude oil, there may be no paraffins at all in the vacuum gas oil fraction. For example, in the paraffinic crude oils, free paraffins will separate as a part of the asphaltene fraction but in the naphthenic crude oils, free paraffins are not expected in the gas oil and asphaltene fractions.

The vestiges of paraffins in the higher-molecular-weight fractions typically occur as alkyl side chains on aromatic and naphthenic systems, and these alkyl chains can contain forty or more carbon atoms.

Paracoumaryl Alcohol

Paracoumaryl alcohol (*p*-coumaryl alcohol) is a phytochemical one of the monolignols. It is a white solid and is a major precursor to lignin or lignans.

Paracoumaryl alcohol (*p*-coumaryl alcohol)

See also: Coniferyl Alcohol, Lignin, Sinapyl Alcohol.

Partial Oxidation

Partial oxidation (often referred to as POX or P_{ox}) is the reaction that occurs when a less-than full stoichiometric fuel-air mixture is partially combusted in a reformer, creating a hydrogen-rich synthesis gas (syngas), which can then be put to further use, for example in the production of hydrocarbon fuels or oxygenates. In fact, the majority of gasifiers are partial oxidation reactors, in which just sufficient air or oxygen is introduced to burn part of the input biomass to provide the heat for pyrolysis and gasification.

For example, the combustion of a carbonaceous feedstock such as coal involves reaction with oxygen, which may be supplied as pure oxygen or as air, and forms carbon monoxide and carbon dioxide. Principal chemical reactions between carbon and oxygen involve:

If sufficient air or oxygen is supplied, combustion proceeds sequentially through vapor-phase oxidation and ignition of volatile matter to eventual ignition of the residual char. Certainly, it is not desirable to carry out the combustion reaction too much since it represents a wasteful use of carbonaceous resources.

Even though the combustion or oxidation reactions of carbon may be expressed in terms of simple stoichiometric reaction equations, partial oxidation involves a complex reaction mechanism that depends on how fast and

efficiently combustion progresses. The reaction pathway is further complicated due to the presence of both gas-phase homogeneous reactions and heterogeneous reactions between gaseous and solid reactants. The early controversy involving the carbon oxidation reaction centered on whether carbon dioxide is a primary product of the heterogeneous reaction of carbon with oxygen or a secondary product resulting from the gas-phase oxidation of carbon monoxide. Oxidation of carbon involves at least the following four carbon-oxygen interactions of which only two are stoichiometrically independent:

It is generally agreed concerning the carbon-oxygen reaction that (i) carbon dioxide, as well as carbon monoxide, is a primary product of carbon oxidation, (ii) the ratio of the primary products, carbon monoxide to carbon dioxide, is generally found to increase sharply with increasing temperature, and (iii) there is lack of general agreement in that the magnitude of the ratio of the primary products is a sole function of temperature and independent of the carbon reacted.

A distinction is made between thermal partial oxidation (TPOX) and catalytic partial oxidation (CPOX). For example, thermal partial oxidation reactions, which are dependent on the air-fuel ratio, proceed at temperatures in excess of 1,200°C (2,190°F). In catalytic partial oxidation, the use of a catalyst reduces the required temperature to approximately 800 to 900°C (1,470 to 1,650°F).

The choice of method depends on the sulfur content of the fuel being used – catalysts can be employed if the sulfur content is below 50 ppm – higher sulfur content would poison the catalyst, and the thermal method is preferable for such fuels.

Particulate Matter

Particulate matter (particulates, fine particles) are tiny particles of solid or liquid suspended in a gas. Some particulates occur naturally, originating from volcanoes, dust storms, forest and grassland fires, living vegetation, and sea spray. Human activities, such as the burning of fossil fuels in vehicles, power plants, and various industrial processes also generate significant amounts of aerosols. Averaged over the globe, anthropogenic aerosols – those made by human activities – currently account for approximately 10% of the total amount of aerosols in the atmosphere. Increased levels of fine particles in the air are linked to health hazards.

The detrimental environmental effects of particulate matter on the atmosphere have been of some concern for several decades. The total output of particulate matter into the atmosphere has increased in Europe since medieval times and, although the sources are various, there is special concern because of the issue of particulate matter from fossil fuel use. Species such as mercury, selenium, and vanadium which can be ejected into the atmosphere as a result of fossil fuel combustion are particularly harmful to the flora and fauna. There is the need to remove such materials from gas streams that are generated during fossil fuel processing and use.

The most common categorizations imposed on particulates are those with respect to size. The most widely used definition is the aerodynamic diameter. The notation PM10 is used to describe particles of 10 micrometers or less, and PM2.5 represents particles less than 2.5 micrometers in aerodynamic diameter. However, all reference methods allow a high margin of error which is referred to with other equivalent numeric values (Table P-1).

Table P-1 Size ranges for particulate matter.

Fraction designation	Size Range microns (μm)
PM ₁₀	Less than or equal to 10
PM _{2.5}	Less than or equal to 10
PM ₁	Less than or equal to 10
Ultrafine (UFP or UP)	Less than or equal to 10
PM ₁₀ -PM _{2.5} (coarse fraction)	2.5 μm to 10

In some specialized settings, each fraction may exclude the fractions of lesser scale, so that PM₁₀ excludes particles in a smaller size range, e.g., PM_{2.5}, usually reported separately. Such a case is sometimes emphasized with the difference notation, e.g., PM₁₀-PM_{2.5}.

Particulate matter consists of the minute separate airborne particles that are emitted from oil shale operations. Particulate matter is one of the criteria pollutants under the Clean Air Act.

See also: Gas Cleaning, Gas Processing, Gas Treating, Particulate Matter Control, Particulate Matter Removal.

Particulate Matter Control

Particulate matter control (often referred to as dust control) has been one of the primary concerns of industries, since the emission of particulate matter is readily observed through the deposition of fly ash and soot as well as in impairment of visibility. Differing ranges of control can be achieved by use of various types of equipment. Upon proper characterization of the particulate matter emitted by a specific process, the appropriate piece of equipment can be selected, sized, installed, and performance tested.

Particulate matter (PM) control technologies include electrostatic precipitators (ESPs), fabric filters (FFs) (also called “baghouses”), and particulate scrubbers (PS). Electrostatic precipitators and fabric filters may be classified as either cold-side (CS) devices – installed upstream of the air heater where flue gas temperatures range from 140 to 160°C (285 to 320°F) – or hot-side – installed downstream of the air heater and operate at temperatures ranging from 350 to 450°C (650 to 840°F).

See also: Gas Cleaning, Gas Processing, Gas Treating, Particulate Matter, Particulate Matter Removal.

Particulate Matter Removal

There are many types of particulate collection devices in use, and they involve a number of different principles for removal of particles from gas streams. Selection of an appropriate particle removal device must be based upon equipment performance as anticipated/predicted under the process. Such equipment includes cyclone collectors, electrostatic precipitators, and wet scrubbers.

Cyclones collectors utilize the principle of centrifugal force to separate particulates from a gas stream. Vortex flow is induced by the design of the gas inlet duct, and the main vortex is characterized by axial flow away from the gas inlet and radial flow outward from the ads of the cyclone body. The central core has the same rotary direction, but the axial and radial velocity components are in the opposite direction to that of the main vortex. The major requirements of the dust discharge are that upward gas flow into the cyclone body should be minimal, while continuous discharge of the dust is maintained. This is often accomplished by the inclusion of baffles or straightening vanes at the discharge to suppress the vortex at this point, thus minimizing up-flow.

Cyclones have many potential applications in coal gasification systems. Efficiency can be low for collecting particles smaller than 10 microns, but above this size, collection efficiency can be at least 90%. Conventional applications for cyclones include use as precleaners, entrainment separators, and for controlling dust emissions from coal grinding and pulverizing.

Electrostatic precipitators are efficient collectors of fine particulate matter and are capable of reducing the amount of submicron particles by 90%, or more. They have the capability of collecting liquid mists as well as dust. The basic components of a precipitator are the discharge (or corona) electrode, the collection electrode (plates), and the precipitator shell. Other components are the dust hopper, high-voltage equipment, and gas distributors. Suspended particles are charged by collisions with the negative ions passing through the zone between the corona and the collection electrode. Movement of the particles to the collection electrode is governed by the interaction of the electric field and charged particles in the moving gas stream.

Granular-bed filters use a bed of separate, packed granules which serve as the filter medium and have the ability to collect particulates from gas streams not only at low-temperatures but also (depending on bed structure) at high temperature and pressure. These filters (again depending on bed characteristics) can be used for simultaneous control of particulates and hydrogen sulfide (by adsorption) high temperature.

Granular bed filters are classified according to the method used to remove collected dust from the filter medium, thus: (i) continuously moving, (ii) intermittently moving, or (iii) fixed-bed filters. Cleaning is required to prevent interstitial plugging, which can cause pressure drop. This requirement distinguishes granular bed filters from fluidized-bed systems, which utilize the product gas to keep the granules in motion and prevent plugging.

Continuously moving systems may be arranged in a cross-flow configuration in which the gas passes horizontally through the granular layer, while the granules and collected dust move continuously downward and are collected at the bottom. The dust and granules are then separated and the cleaned granules returned to the bed. In the intermittently moving-bed concept, the bed is stationary during filtration. Accumulated dust and the surface layer of granules are removed from the panel by a backwash pulse and replaced by fresh granules from the overhead hoppers. Fixed-bed systems use either backwash air and/or mechanical agitation to remove collected dust.

Wet scrubbers are used when hot raw gas is to be cooled directly or if it has already been cooled in a waste-heat recovery system. Wet scrubbers are devices that utilize gas/liquid contacting to cool the gas stream, condense high-boiling hydrocarbon derivatives, dissolve some constituents, and separate particles from gas streams. There are many different wet scrubber designs, and a type that has been widely applied to coal gas is the venturi scrubber. Gas streams are passed through a tube to contact with water, which is added at the throat. The throat promotes intimate mixing of the gas and liquid. The liquid, which forms droplets ranging in size from 100 to 1,000 microns, collects particulates mainly by inertial impaction.

Other wet scrubber designs that can be applied to coal gas are plate scrubbers (sieves, bubble caps, and impingement plates), massive packing (rings, saddles), fibrous packing (plastic, spun glass, fiber glass, and steel wool), centrifugal (cyclone), and directional baffles (louvres, zigzags, disk, and donut).

Peanut Oil

Peanut oil, also known as groundnut oil or arachis oil, is a vegetable oil-derived from peanuts. There are several varieties of peanut oil on the market today. From refined, 100% peanut oil to blends of oil.

Refined peanut oil is the most common form of peanut oil used for cooking. This oil has been refined to remove flavors and colors, making it a neutral oil. Virgin or cold-pressed peanut oil is oil that has not been refined and retains much of the properties. Roasted peanut oil is the oil-derived peanuts that have been roasted prior to expelling the oil, which provides a deep nutty flavor and dark golden brown color. Peanut oil blends are the results of blending peanut oil with other natural oils, such as soybean oil.

The various varieties of peanuts may be the future of peanut biodiesel because it can be planted and grown with just one herbicide application for weed control, compared to the three to four applications typically sprayed during a growing season for edible peanuts. Additionally, these fuel peanuts are grown without fungicides, which are the greatest input cost in traditional peanut production. Promising varieties also include DP-1 and Georgia-04S, a new high-oleic-acid, Spanish-type peanut. Production of these peanuts would be limited to the southern regions of the United States where growing conditions are more suitable.

Peanut oil, also known as groundnut oil or arachis oil, is composed of fatty acids such as oleic acid, palmitic acid, and other fatty acids.

Peanut oil could be used as a source of fuel for the diesel engine and was one of the earliest demonstrations of biodiesel technology.

See also: Biodiesel.

Peat

Peat, while being generally assigned as a precursor to coal (in fact, it is the bottom rung of the coal origin and maturation ladder) is also considered as a plentiful supply (when treated in the appropriate manner) of alternate fuels and an alternate source of energy.

Peat is partially matured plant matter, formed by slow decay in water such as found in locations variously called bogs, moors, muskegs, pocosins, mires, and peat swamps. Peat forms when plant material, usually in marshy areas, is inhibited from decaying fully by acidic and anaerobic conditions. It is composed mainly of marshland vegetation: trees, grasses, fungi, as well as other types of organic remains, such as insects, and animal corpses, which may be of some value to archaeologists.

Peat layer growth and the degree of decomposition (or humification) depends principally on its composition and on the degree of waterlogging. Peat formed in very wet conditions accumulates considerably faster, and is less decomposed, than that in drier places. This allows climatologists to use peat as an indicator of climatic change. The composition of peat can also be used to reconstruct ancient ecologies by examining the types and quantities of its organic constituents.

Peat material is fibric, hemic, or sapric. Fibric peat is the least decomposed, and comprise intact fiber. Hemic peat is somewhat decomposed, and sapric peat is the most decomposed. Phragmites peat is composed of reed grass (*Phragmites australis*) and other grasses and is denser than many other types of peat.

Peat is soft and easily compressed when water in the peat is forced out. When dried, peat can be used as a fuel and has industrial importance as a fuel in some countries, such as Ireland and Finland, where it is harvested on an industrial scale. Although peat has many uses, it also presents severe problems at times. When dry, it can be a major fire hazard, as peat fires can burn almost indefinitely (or at least until the fuel is exhausted), even underground, provided there is a source of oxygen. Peat deposits also pose major difficulties to builders of structures, roads, and railways, as they are highly compressible under even small loads.

See also: Peat Swamp and Peat Swamp Forest.

Peat Swamp and Peat Swamp Forest

The term peat swamp (in reality, a complex chemical and environmental entity) is used to mean the initial products of the anaerobic decay of the fallen trees (woody material). It is not, however, meant to show any compliance with the consecutive theory in which peat is gradually converted (metamorphosed) to coal by a series of sequential chemical and physical transformations. The converse is also true insofar as use of convenient, perhaps archaic, terminology does not mean rejection of a theory which advocates the concepts of concurrent chemical transformation without the insertion of coal-types as intermediate products in the sequence.

Peat swamp forests are tropical moist forests where waterlogged soil prevents dead leaves and wood from fully decomposing. Over time, this creates a thick layer of acidic peat. Large areas of these forests are being logged at high

rates. Peat swamp forests are typically surrounded by lowland rain forests on better-drained soils, and by brackish or salt-water mangrove forests near the coast.

Tropical peatlands, which coexist with swamp forests within the tropical and subtropical moist broadleaf forests biome, store and accumulate vast amounts of carbon as soil organic matter. In fact, tropical peatlands has important implications for climate change; they are among the largest near-surface reserves of terrestrial organic carbon. Peat swamp forests, which have ecological importance, are one of the most threatened, yet least studied and most poorly understood biotypes.

Tropical peat swamp forests are home to thousands of animals and plants, including many rare and critically endangered species such as the orangutan and Sumatran tiger, whose habitats are threatened by peatland deforestation.

See also: Peat.

Pelletization

Pelletization (pelletizing) is the formation of pellet-like products from solid carbonaceous materials such as char and coke. The materials used for pelletizing fuels generally have a size consistency below 0.004 inch, and the majority of the particles are smaller than 0.002 inch. Addition of liquid on rotating disks or drums agglomerates the fuel to spherical shapes. The strength of the pellets depends on the water content of the agglomerated material and is greatest when the optimum action of the capillary forces of the water is obtained.

A cold pelletizing process for the carbonization of char or coke pellets involves heating the pellets at heated to 550 to 650°C (1,020 to 1,200°F) and subsequently carbonized with sand as heat carrier. In the second stage, the pellets are coated with hematite ore (Fe_2O_3) and the ore-covered pellets are then coked whereupon soften and sinter together to form a coherent coke. Addition of a high-boiling oil to the char/coke increases the stability of the pellets in the oven.

A hot pelletizing process shapes the pellet in the chosen temperature range, possibly in the presence of binder, using pelletizing equipment. An advantage is the possibility of mixing in larger amounts of binder than can be done in briquetting. The binder cokes at the temperatures that are used during pellet shaping, and the possibility of desulfurizing the coke pellets during calcining is possible by addition of hydrogen under pressure.

Pellets and Briquettes

Pellets are a fuel in the form of short cylindrical or spherical units. It is usually 6-12 mm in diameter and 10-30 mm in length, with a moisture content of less than 10%.

Pellets are generally produced from residues of wood processing industries and mainly used for heating and electricity production purposes. Pellets are especially suitable in small heating systems due to their automatic heating process, easy storage as they do not degrade, relatively low cost, and a low yield of ash.

From the three most commonly used types of wood (logs, wood chips, and wood pellets), pellets offer major advantages for small heating systems and together with wood chips (which, contrary to pellets, are best suited for a large-scale use) are a best renewable fuel alternative to fossil fuels in the future. This type of bioenergy is efficient, clean, and reliable. In comparison with other solid biofuels, pellets provide the following advantages and disadvantages:

Pellets are generally manufactured from sawdust – a by-product of sawmilling, shavings, grinding dust, bark, and finely reduced wood waste, some of which comes from further processing of wood chips.

The demand for pellets is increasing, and other biomass wastes will be considered as raw materials. Therefore, logging residues, energy crops, and its residues (ex. straw), agricultural waste, and other organic fractions of household waste could be used for pellet production.

However, these new fuels might release a higher amount of emissions due to incomplete combustion, so their use must be studied carefully before introduction to the residential market.

In general, wood pellets can be produced from 4 main types of biomass: woody biomass, herbaceous biomass, fruit biomass, and peat.

Pellets made of compressed sawdust or wood shavings have been available in many parts of the world for more than several decades. Because they are compressed, pellets offer a more concentrated form of fuel than wood chips. Consequently, they need less storage space and are easier to handle. The manufacture of wood pellets requires more energy than woodchips, and the capital cost for production plant is high; pellets are therefore more expensive than chips.

Pellets can be used to fuel a variety of appliances and heating systems. The smallest are pellet stoves with outputs of up to around 9 kW which are suitable for heating individual rooms. These stoves are electronically controlled and can deliver regulated heat output and only need fueling once every few days. Pellet boilers are available in a wide range of outputs from small domestic scale to large industrial scale.

See also: Briquettes, Briquetting, Pelletization.

Percolation Filtration Process

The term percolation refers to the movement of fluids through porous materials, and filtration is the act or process of filtering which is the mechanical separation of the undissolved particles floating in a liquid. Thus, the percolation filtration process is a continuous-flow cyclic-regenerative liquid phase process in which oil is filtered through a bed (containing 10 to 50 tons of Fuller's earth – a clay mineral) before storage. Two or more beds are used alternately on an operating and regenerating cycle. The spent clay is regenerated by washing it with naphtha, steaming, and burning.

Activated Fuller's earth used in the percolation filter process is in the granular form; this process is usually used for light color oils like base oil distillates.

The percolation method is a simple process and consists of a vertical steel cylinder closed at both ends and provided with suitable man-heads and pipe connections at the top and bottom to permit the introduction and discharge of clay and oil. A perforated plate or a wire screen at a slight distance above the bottom is provided over which a heavy canvas blanket is placed and clamped to hold the clay in filter yet allow oil to pass through and out of the filter.

See also: Clay Minerals.

Perennial Systems for Biofuel Production

Several woody perennial plants can be grown for bio-fuels, while at the same time provide conservation benefits and ecological services that markedly exceed those associated with conventional annual crops like corn. In the United States, most research has focused willow shrubs (*Salix* spp.) and hybrid poplar (*Populus* spp.) production systems.

Hybrid poplars are predominantly cottonwoods and interspecific hybrids that have been selected and bred for fast growth. Sustained yields of 5 dry tons/acre/year have been documented in the north central United States and have reached 7 dry tons/acre/year on high productivity sites.

Another potentially large source of cellulose is agricultural residues (such as corn stalks), but the extent to which these can be sustainably removed from crop land each year without significantly lowering soil organic matter and overall soil quality is not fully appreciated.

Timber belts are multiple row field windbreaks that are planted with commercially valuable, fast-growing trees (such as hybrid poplar or hybrid willow) to provide conservation benefits, improve adjacent crop yields, diversify on-farm income sources, and produce commercially valuable wood products. Various planting configurations have been developed that provide wind protection for soils and crops, and yield sufficient biomass to make wood harvest economical. Tree rows are oriented perpendicular to the prevailing wind to reduce wind velocity and improve the microclimate within the sheltered zone to enhance production of adjacent crops. Because of their rapid growth and range of marketable products, hybrid poplars fit well into the timber belt concept. The strategy is to harvest half of the rows in a timber belt at age 7 to 12, while the other half are left to provide continued wind protection. Within a few years, after the stumps have sprouted and re-established sufficient wind protection, the remaining rows are harvested. In this way, continuous wind protection and associated economic benefits to adjacent crops can be achieved.

Willow has several characteristics that make it ideal for woody crop systems, including high yields, ease of propagation, a broad genetic base, a short breeding cycle, and the ability to resprout after multiple harvests. A sustainable system has been devised for willow biomass production by planting unrooted stem cuttings at a density of 4,000-8,000 plants per acre. Willow can achieve high yields, typically reaching 15-25 feet in height in three years, at which time they can be harvested using modified agricultural equipment that cuts and chips the biomass in one operation. They resprout vigorously from their stumps (coppice) following harvest, with 7 to 8 harvesting cycles possible from an initial planting.

Peri-Condensed Aromatic Compounds

Peri-condensed aromatic compounds are based on angular condensed aromatic hydrocarbon systems, e.g., phenanthrene and chrysene are examples, and similar homologs, while anthracene and tetracene are examples of linear condensed aromatic hydrocarbon systems:

Phenanthrene

Chrysene

Anthracene

Tetracene

Periodic Table of the Elements

The Periodic Table of the Elements is an important reference item since it arranges all the known elements in an informative manner (Table P-2). The elements are arranged left to right and top to bottom in order of increasing atomic number, and the order generally coincides with increasing atomic mass. The different rows of elements are called periods, and the period number of an element signifies the highest energy level an electron in that element occupies (in the unexcited state). The number of elements in a period increases as one traverses down the periodic table because as the energy level of the atom increases, the number of energy sub-levels per energy level increases.

It is possible – using the data in the table – to extract information concerning individual elements. For instance, by examining the position of an element on the periodic table, it is possible to make an inference related to the electronic configuration of the element. Elements that lie in the same column on the periodic table (referred to as a

group) have identical valance electron configurations and consequently behave in a similar fashion chemically. The definitions related to the Periodic Table are as follows.

Atomic Number

The atomic number of an element, the number of protons in an atom, defines what element it is. For example, carbon atoms have six protons, hydrogen atoms have one, and oxygen atoms have eight. The number of protons in an atom is referred to as the atomic number of that element. The number of protons in an atom also determines the chemical behavior of the element.

Table P-2 The Periodic Table of the Elements.

1 H																		2 He

Atomic Symbol

The atomic symbol is one or two letters chosen to represent an element (such as H for hydrogen), and these symbols are used internationally. Typically, a symbol is the truncated name of the element or the truncated Latin name of the element.

Atomic Mass

The atomic mass is the average mass of an element in atomic mass units (amu). Though individual atoms always have an integer number of atomic mass units, the atomic mass on the Periodic Table is stated as a decimal number because it is an average of the various isotopes of an element. Isotopes can have a weight either more or less than the average. The average number of neutrons for an element can be calculated by subtracting the number of protons (atomic number) from the atomic mass.

Electronic Configuration

The electronic configuration is the orbital description of the locations of the electrons in an unexcited atom. In fact, it can be predicted how an atom will react based upon the electron configuration, and properties such as stability, boiling point, and conductivity can be predicted. Typically, only the outermost electron shells matter in reaction chemistry, so the inner electron shell notation can be truncated by replacing the long-hand orbital description with the symbol for a noble gas in brackets. This method of notation vastly simplifies the description for large molecules.

See also: Heavy Metals.

Permeability

Permeability (the unit of permeability is the Darcy) is the property of solids (such as rocks and in some cases, catalysts) that is an indication of the ability for fluids (gas or liquid) to flow through the solid. High permeability will

allow fluids to move rapidly through solid. For example, sandstones may vary in permeability from less than one to over 50,000 millidarcies (md). Permeabilities are more commonly in the range of tens to hundreds of millidarcies. A solid with 25% porosity and a permeability of 1 md will not yield a significant flow of water.

The effective permeability: a relative measure of the conductivity of a porous medium for a fluid when the medium is saturated with more than one fluid. A fundamental principle is that the total of the effective permeability is less than or equal to the absolute permeability which is the ability of a solid to conduct a fluid when only one fluid is present in the pores of the rock.

See also: Porosity.

Petrochemicals

The chemical industry is in fact the chemical process industry by which a variety of chemicals are manufactured. The chemical process industry is, in fact, sub-divided into other categories that are (i) chemicals and allied products in which chemicals are manufactured from a variety of feedstocks and may then be put to further use, (ii) rubber and miscellaneous products which focuses on the manufacture of rubber and plastic materials, and (iii) crude oil refining and related industries. The petrochemical industry falls under the sub-category of crude oil and related industries.

The term petrochemicals is often applied to individual chemicals produced from crude oil (Table P-3, Table P-4) which are then used as precursors to a wide range of other products such as polymers and plastics. Also, natural product chemicals as might constitute the various type of biomass could conceivably be the starting point for a biomass-based petrochemicals industry. In fact, biomass gasification leading to product gases suitable for the production of chemicals by the Fischer-Tropsch process is well documented.

Table P-3 Production of petrochemicals during refining.

Starting material	Process	Product
Petroleum	Distillation	Light ends
		methane
		ethane
		propane
		butane
	Catalytic cracking	ethylene
		propylene
		butylenes
		higher olefins
		ethylene
coking	propylene	
	butylenes	
	higher olefins	
Natural gas	refining	methane
		ethane
		propane
		butane

However, the definition of petrochemicals has been broadened to include the whole range of organic chemicals including chemicals from renewable energy sources. In many instances, a specific chemical included among the petrochemicals may also be obtained from other sources, such as coal, coke, or vegetable products. For example, materials such as benzene and naphthalene can be made from either crude oil or coal, while ethyl alcohol may be of petrochemical or vegetable origin. This makes it difficult to categorize a specific substance as, strictly speaking, petrochemical or non-petrochemical.

Table P-4 Properties of selected petrochemicals.

	Molecular weight	Specific gravity	Boiling point	Ignition temperature	Flash point	Flammability limits in air
			degrees F	degrees F	degrees F	% v/v
Benzene	78.1	0.879	176.2	1040	12	1.35-6.65
n-Butane	58.1	0.601	31.1	761	-76	1.86-8.41
iso-Butane	58.1		10.9	864	-117	1.80-8.44
n-Butene	56.1	0.595	21.2	829	Gas	1.98-9.65
iso-Butene	56.1		19.6	869	Gas	1.8-9.0
Ethane	30.1	0.572	-127.5	959	Gas	3.0-12.5
Ethylene	28.0		-154.7	914	Gas	2.8-28.6
n-Hexane	86.2	0.659	155.7	437	-7	1.25-7.0
n-Heptane	100.2	0.668	419.0	419	25	1.00-6.00
Methane	16.0	0.553	-258.7	900-1170	Gas	5.0-15.0
Naphthalene	128.2		424.4	959	174	0.90-5.90
Neohexane	86.2	0.649	121.5	797	-54	1.19-7.58
Neopentane	72.1		49.1	841	Gas	1.38-7.11
n-Octane	114.2	0.707	258.3	428	56	0.95-3.2
iso-Octane	114.2	0.702	243.9	837	10	0.79-5.94
n-Pentane	72.1	0.626	97.0	500	-40	1.40-7.80
iso-Pentane	72.1	0.621	82.2	788	-60	1.31-9.16
n-Pentene	70.1	0.641	86.0	569	-	1.65-7.70
Propane	44.1		-43.8	842	Gas	2.1-10.1
Propylene	42.1		-53.9	856	Gas	2.00-11.1
Toluene	92.1	0.867	321.1	992	40	1.27-6.75
Xylene	106.2	0.861	281.1	867	63	1.00-6.00

Petrochemicals are chemicals derived from natural gas and crude oil and, for convenience of identification, petrochemicals can be divided into two groups: (i) primary petrochemicals and (ii) intermediates and derivatives. Primary petrochemicals include olefin derivatives (ethylene, propylene, and butadiene), aromatic derivatives (benzene, toluene, and xylenes), and methanol. Petrochemical intermediates are generally produced by chemical conversion of primary petrochemicals to form more complicated derivative products. Petrochemical derivative products can be made in a variety of ways: directly from primary petrochemicals; through intermediate products which still

contain only carbon and hydrogen; and, through intermediates which incorporate chlorine, nitrogen, or oxygen in the finished derivative. In some cases, they are finished products; in others, more steps are needed to arrive at the desired composition.

In addition, there are four general types of petrochemicals: (i) aliphatic compounds, (ii) aromatic compounds, (iii) inorganic compounds, and (iv) synthesis gas (carbon monoxide and hydrogen). Synthesis gas is used to make ammonia (NH_3) and methanol (methyl alcohol, CH_3OH). Ammonia is used primarily to form ammonium nitrate (NH_4NO_3), a source of fertilizer. Much of the methanol produced is used in making formaldehyde ($\text{HCH}=\text{O}$). The rest is used to make polyester fibers, plastics, and silicone rubber.

An aliphatic petrochemical compound is an organic compound that has an open chain of carbon atoms, be it normal (straight), e.g., n-pentane ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$) or branched, e.g., iso-pentane [2-methylbutane, $\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_3$], or unsaturated. The unsaturated compounds, olefins, include important starting materials such as ethylene ($\text{CH}_2=\text{CH}_2$), propylene ($\text{CH}_3\text{CH}=\text{CH}_2$), butene-1 ($\text{CH}_3\text{CH}_2\text{CH}_2=\text{CH}_2$), iso-butene (2-methylpropene [$\text{CH}_3(\text{CH}_3)\text{C}=\text{CH}_2$]), and butadiene ($\text{CH}_2=\text{CHCH}=\text{CH}_2$).

Ethylene is the hydrocarbon feedstock used in greatest volume in the petrochemical industry. From ethylene, for example, are manufactured ethylene glycol, used in polyester fibers and resins and in antifreezes; ethyl alcohol, a solvent and chemical reagent; polyethylene, used in film and plastics; styrene, used in resins, synthetic rubber, plastics, and polyesters; and ethylene dichloride, for vinyl chloride, used in plastics and fibers. Propylene is also an important source of petrochemicals and is used in making such products as acrylics, rubbing alcohol, epoxy glue, and carpets. Butadiene is used in making synthetic rubber, carpet fibers, paper coatings, and plastic pipes.

An aromatic petrochemical is also an organic chemical compound but one that contains, or is derived from, the basic benzene ring system.

The petrochemical industry has grown with the crude oil industry and is considered by some to be a mature industry. However, as is the case with the latest trends in changing crude oil types, it must also evolve to meet changing technological needs. The manufacture of chemicals or chemical intermediates from a variety of raw materials is well established. And the use of natural gas and crude oil is an excellent example of the conversion of such raw materials to more valuable products. The individual chemicals made from natural gas and crude oil are numerous and include industrial chemicals, household chemicals, fertilizers, and paints, as well as intermediates for the manufacture of products, such as synthetic rubber and plastics.

Petrochemicals are generally considered chemical compounds derived from crude oil either by direct manufacture or indirect manufacture as by-products from the variety of processes that are used during the refining of crude oil. Gasoline, kerosene, fuel oil, lubricating oil, wax, asphalt, and the like are excluded from the definition of petrochemicals, since they are not, in the true sense, chemical compounds but are in fact intimate mixtures of hydrocarbon derivatives.

Petrochemicals are made, or recovered from, the entire range of crude oil fractions, but the bulk of petrochemical products are formed from the lower-boiling (C_1 to C_4) hydrocarbon gases as raw materials. These materials generally occur in natural gas, but they are also recovered from the gas streams produced during refinery, especially cracking, operations. Refinery gases are also particularly valuable because they contain substantial amounts of olefins that, because of the double bonds, are much more reactive than the saturated (paraffin) hydrocarbon derivatives. Also important as raw materials are the aromatic hydrocarbon derivatives (benzene, toluene, and xylene), that are obtained in rare cases from crude oil and, more likely, from the various product streams. By means of the catalytic reforming process, non-aromatic hydrocarbon derivatives can be converted to aromatics by dehydrogenation and cyclization.

The classification of materials as petrochemicals is used to indicate the source of the chemical compounds, but it should be remembered that many common petrochemicals can be made from other sources, and the terminology is therefore a matter of source identification.

The starting materials for the petrochemical industry are obtained from crude oil in one of two general ways. They may be present in the raw crude oil and, as such, are isolated by physical methods, such as distillation or solvent extraction. On the other hand, they may be present, if at all, in trace amounts and are synthesized during the refining operations. In fact, unsaturated (olefin) hydrocarbon derivatives, which are not usually present in crude oil, are nearly always manufactured as intermediates during the various refining sequences.

The manufacture of chemicals from crude oil is based on the ready response of the various compound types to basic chemical reactions, such as oxidation, halogenation, nitration, dehydrogenation addition, polymerization,

and alkylation. The low-molecular-weight paraffins and olefins, as found in natural gas and refinery gases, and the simple aromatic hydrocarbon derivatives have so far been of the most interest because it is individual species that can be readily be isolated and dealt with. A wide range of compounds is possible; many are being manufactured and progressing to the stage in which a sizable group of products is being prepared from the higher-boiling fractions of crude oil. For example, the various reactions of asphaltene constituents indicate that these materials may be regarded as containing chemical functions and are therefore different and are able to participate in numerous chemical or physical conversions to, perhaps, more useful materials. The overall effect of these modifications is the production of materials that either affords good-grade aromatic cokes comparatively easily or the formation of products bearing functional groups that may be employed as a non-fuel material.

For example, the sulfonated and sulfomethylated materials and their derivatives have satisfactorily undergone tests as drilling mud thinners, and the results are comparable to those obtained with commercial mud thinners. In addition, these compounds may also find use as emulsifiers for the *in situ* recovery of heavy (viscous) crude oil. These are also indications that these materials and other similar derivatives of the asphaltene constituents, especially those containing such functions as carboxylic or hydroxyl, readily exchange cations and could well compete with synthetic zeolites. Other uses of the hydroxyl derivatives and/or the chloro-asphaltene constituents include high-temperature packing or heat transfer media.

Reactions incorporating nitrogen and phosphorus into the asphaltene constituents are particularly significant at a time when the effects on the environment of many materials containing these elements are receiving considerable attention. Here, there is the potential that slow-release soil conditioners only release the nitrogen or phosphorus after considerable weathering or bacteriological action. One may proceed a step further and suggest that the carbonaceous residue remaining after release of the hetero-elements may be a benefit to humus-depleted soils, such as the gray-wooded and solonchic soils. It is also feasible that coating a conventional quick-release inorganic fertilizer with a water-soluble or water-dispersible derivative will provide a slower-release fertilizer and an organic humus-like residue. In fact, variations on this theme are multiple.

Nevertheless, the main objective in producing chemicals from crude oil is the formation of a variety of well-defined chemical compounds that are the basis of the petrochemical industry. It must be remembered, however, that ease of separation of a particular compound from crude oil does not guarantee its use as a petrochemical building block. Other parameters, particularly the economics of the reaction sequences, including the costs of the reactant equipment, must be taken into consideration.

See also: Biochemicals.

pH

The pH value is a means of expressing the acidity or alkalinity of a solution. At normal temperatures, *pure* water has a pH of 7 (neutral); the pH of a strong acid is approximately 1 and that of a strong base approximately 14.

The pH is the cologarithm of the activity of dissolved hydrogen ions (H^+). The hydrogen ion activity coefficients cannot be measured experimentally, so they are based on theoretical calculations. The pH scale is not an absolute scale; it is relative to a set of standard solutions whose pH is established by international agreement. To calculate the pH of an aqueous solution, it is necessary to know the concentration of the hydronium ion in moles per liter (molarity) from which the pH can be calculated using the expression:

$$pH = -\log [H_3O^+]$$

Also, the hydronium ion concentration can be calculated from the pH of the solution by the reverse of the mathematical operation employed to find the pH. Thus:

$$[H_3O^+] = 10^{-pH}$$

$$\text{or } [H_3O^+] = \text{antilog } (-pH)$$

pH is an important quantity that reflects the chemical conditions of a solution. The pH can control the availability of nutrients, biological functions, microbial activity, and the behavior of chemicals.

See also: Acidity and Alkalinity.

Phenol

Phenol (C_6H_5OH) is a key industrial chemical; however, the output of phenol from coal tar is exceeded by that of synthetic phenol.

Phenol has a low melting point (Table P-5); it crystallizes in colorless prisms and has a characteristic, slightly pungent odor. In the molten state, it is a clear, colorless, mobile liquid. At low temperature ($<68^{\circ}C$, $<154^{\circ}F$), the miscibility of phenol with water is limited, but above this temperature, the two are completely miscible.

Table P-5 Selected properties of phenol.

Chemical formula	C_6H_5O
Molar mass	$94.113 \text{ g}\cdot\text{mol}^{-1}$
Appearance	Transparent crystalline solid
Density	$1.07 \text{ g}/\text{cm}^3$
Melting point	$40.5^{\circ}C$ ($104.9^{\circ}F$; 313.6 K)
Boiling point	$181.7^{\circ}C$ ($359.1^{\circ}F$; 454.8 K)
Solubility in water	$8.3 \text{ g}/100 \text{ mL}$ ($20^{\circ}C$)
Vapor pressure	0.4 mmHg ($20^{\circ}C$) ^[3]

The melting and solidification points of phenol are quite substantially lowered by water. Phenol is readily soluble in most organic solvents (aromatic hydrocarbons, alcohols, ketones, ethers, acids, halogenated hydrocarbons, etc.) and somewhat less soluble in aliphatic hydrocarbons. Phenol forms azeotropic mixtures with water and other substances.

Phenol is used for the production of phenol-formaldehyde resins, while other important uses in the plastics field include the production of polyamides such as nylon, of epoxy resins and polycarbonates based on bisphenol A and of oil-soluble resins from p-t-butyl and p-octyl phenols. It is also used in the manufacture of pentachlorophenol which is used as a fungicide and in timber preservation. Aspirin and many other pharmaceuticals, certain detergents, and tanning agents are all derived from phenol, and another important use is in the manufacture of 2,4-dichlorophenoxyacetic acid (2,4-D) which is a selective weed-killer.

Phosphate Desulfurization

The phosphate desulfurization process uses potassium phosphate (K_3PO_4) as the active agent and is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbon derivatives as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Photolytic Oxidation Process

The photolytic oxidation process uses light to oxidize organic contaminants. They can be used in conjunction with chemical oxidizers. One technique that works well in many industrial situations is the combination of ultraviolet light and ozone gas. The process has the disadvantage of requiring relatively long residence times.

The photolytic oxidation process indirectly destroys volatile organic compounds (VOCs) in soil and groundwater. The process uses a xenon pulsed-plasma flash-lamp that emits short wavelength ultraviolet (UV) light at high intensity. The process strips the contaminants into the vapor phase, and the UV treatment converts the volatile organic compounds into less hazardous compounds.

Photolysis occurs when contaminants absorb sufficient UV light energy, transforming electrons to higher energy states and breaking molecular bonds. Hydroxyl radicals, however, are not formed. The process requires the UV light source to emit wavelengths in the regions absorbed by the contaminant.

The process uses vacuum extraction or air stripping to volatilize volatile organic compounds from soils or groundwater, respectively. Volatile organic compounds then enter the photolysis reactor, where a xenon flash lamp generates UV light. The plasma is produced by pulse discharge of electrical energy across two electrodes in the lamp. Ninety-nine percent destruction occurs within seconds, allowing continuous operation. Because organics are destroyed in the vapor phase, the process uses less energy than a system treating dissolved organics.

Photon

The photon is a type of elementary particle which is without mass and, hence, always moves at the speed of light in a vacuum. Photons are emitted in many natural processes. For example, when a charge is accelerated, it emits synchrotron radiation.

The photon is the quantum of the electromagnetic field including electromagnetic radiation such as light and radio waves, and the force carrier for the electromagnetic force. Photons are without mass (massless) and, thus, move at the speed of light in vacuum (approximately 186,282 miles per second). The photon belongs to the class of bosons. Like all elementary particles, photons are currently best explained by quantum mechanics and exhibit wave-particle duality, their behavior featuring properties of both waves and particles.

During a molecular, atomic, or nuclear transition to a lower energy level, photons of various energy will be emitted, ranging from radio waves to gamma rays. Photons can also be emitted when a particle and the corresponding antiparticle are annihilated as, for example, in the electron-positron annihilation.

See also: Boson, Electron, Nuclear Energy, Positron.

Photosynthesis

Photosynthesis is the principle agent for biomass production. In the process, light energy is used by chlorophyll-containing green plants to remove (or fix) carbon dioxide from the atmosphere and convert it to energy-rich organic compounds or biomass. Carbohydrate derivatives are usually the primary constituent of biomass, and cellulose is the single most important component. Starches are also important and predominate in storage organs such as tubers and rhizomes. Sugars reach high levels in fruits and in plants such as sugar cane and sugar beet. Lignin is a significant non-carbohydrate constituent of woody plant biomass.

Chemically, photosynthesis is the process by which chlorophyll-containing cells in green plants convert incident light to chemical energy, capturing carbon dioxide in the form of carbohydrates.

Photosynthesis takes place primarily in plant leaves, and little to none occurs in stems, etc. The parts of a typical leaf include the upper and lower epidermis, the mesophyll, the vascular bundle(s) (veins), and the stomates. The upper and lower epidermal cells do not have chloroplasts and, thus, photosynthesis does not occur there. They serve

primarily as protection for the rest of the leaf. The stomates are holes which occur primarily in the lower epidermis and are for air exchange: they let carbon dioxide in and oxygen out. The vascular bundles or veins in a leaf are part of the transportation systems of plants, moving water and nutrients around the plant as needed. The mesophyll cells have chloroplasts, and this is where photosynthesis occurs.

See also: Plants.

Photovoltaics

Photovoltaics (often abbreviated as PV) is the direct conversion of sunlight to electricity. Considered by many to be the most promising of the renewable electric technologies in the long term, it is an attractive alternative to conventional sources of electricity for many reasons: it is silent and non-polluting, requires no special training to operate, is modular and versatile, has no moving parts, and is reliable and largely maintenance-free. It can be installed almost anywhere, uses both direct and diffuse radiation, and can be incorporated into a variety of building products (roofing tiles and shingles, facades, overhangs, awnings, windows, atriums). Thus, the photovoltaic effect refers to the creation of an electrical current when light shines on a photosensitive material connected in an electrical circuit.

A photovoltaic cell (often called a solar cell) consists of layers of semiconductor materials with different electronic properties. In most of the current solar cells, the semiconductor is silicon, an abundant element in the crust of the Earth. By doping (i.e., chemically introducing impurity elements) most of the silicon with boron to give it a positive or p-type electrical character, and doping a thin layer on the front of the cell with phosphorus to give it a negative or n-type character, a transition region between the two types of doped silicon is formed that contains an electric field. This transition region is called a junction.

Light consists of energy packets called photons, and when light is incident on the cell, some of the photons are absorbed in the region of the junction and energy is transferred to the semiconductor, freeing electrons in the silicon. If the photons have enough energy, the electrons will be able to overcome the opposing electric field at the junction and move freely through the silicon and into an external circuit. These electrons stimulate current flow in the external circuit; the energy can be converted into work.

Photovoltaic systems for specific applications are produced by connecting individual modules in series and parallel to provide the desired voltage and current. Each module is constructed of individual solar cells also connected in series and parallel. Modules are typically available in ratings from a few peak watts to 250 peak watts.

Commercially available photovoltaic systems often include modules made from single-crystal or polycrystalline silicon or from thin layers of amorphous (non-crystalline) silicon. The thin-film modules use considerably less semiconductor material but have lower efficiencies for converting sunlight to direct-current electricity. Cells and modules are made from other thin-film photovoltaic materials.

Amorphous silicon modules experience a conversion efficiency loss of approximately 10% when initially exposed to sunlight, but then stabilize at the reduced figure. The mechanism for this reduction is being actively investigated, but is still not well understood. Individual modules made with other photovoltaic materials do not exhibit such loss of conversion efficiency, but combinations of modules in arrays do exhibit systematic reductions in power output over their lifetimes. Estimated at approximately 1% per year on average, based on data to date, these reductions are most likely associated with deteriorating electrical connections and non-module electrical components.

Complete photovoltaic systems require other components in addition to the photovoltaic modules. This "balance-of-system" generally includes a support structure for the modules to orient them properly to the sun, an inverter to convert direct-current electricity to alternating-current electricity, a storage system for electrical energy (usually batteries), an electronic charge regulator to prevent damage to the batteries by protecting against overcharging by the photovoltaic array and excessive discharge by the electrical load, and related wiring and safety features.

The output of a solar cell can be increased significantly by concentrating the incident sunlight onto a small area. Commercially available concentrator systems use low-cost lenses, mirrors, or troughs in conjunction with tracking systems to focus sunlight on a small, high efficiency but expensive solar cell. One-axis trackers follow the Sun during the day; two-axis trackers track daily and yearly variations in the Sun's position. The higher cost of the cell and the associated tracking equipment, and the inability to use diffuse radiation, are offset by the higher conversion efficiencies achieved.

The cost of photovoltaic electricity is largely determined by four factors: cost of the PV modules, the efficiency of converting sunlight to electricity, the balance-of-system costs, and the lifetime of the systems. There are many combinations of these factors that provide approximately the same cost of electricity. Modules are now available that are designed to last at least thirty years.

Another scheme that has been proposed for use of photovoltaics is the solar satellite power system. Such a system would place large individual PV arrays (up to ten megawatts peak power) in synchronous orbit around the earth, and beam the collected and converted solar energy through the atmosphere in the form of microwaves to large receiving antennas on Earth. The microwave generators would be powered by the photovoltaic electricity. The microwave energy collected at the surface would then be converted back to electricity for broad distribution.

Photovoltaic Cells

Electricity can be produced from sunlight through a process called the photovoltaic (PV) effect. The term describes a process that produces direct electrical current from the radiant energy of the Sun. The photovoltaic effect can take place in solid, liquid, or gaseous material; however, it is in solids, especially semiconductor materials, that acceptable conversion efficiencies have been found. Solar cells are made from a variety of semiconductor materials and coated with special additives. The most widely used material for the various types of fabrication is crystalline silicon, representing over 90% of global commercial photovoltaic module production in its various forms.

A typical silicon photovoltaic cell (also called a solar cell), with a diameter of 4 in., can produce more than 1 W of direct current (DC) electrical power in full sun. Individual solar cells can be connected in series and parallel to obtain desired voltages and currents. These groups of cells are packaged into standard modules that protect the cells from the environment while providing useful voltages and currents. Photovoltaic modules are extremely reliable because they are solid state and have no moving parts. Silicon photovoltaic cells manufactured can provide over 40 years of useful service life.

Photovoltaic devices are made from semiconductor materials which are materials comprising those elements or compounds that have conductivity intermediate to that of metals or insulators. The three types of material structures commonly used to produce photovoltaics are (i) amorphous, with no order or periodicity within the compound, (ii) polycrystalline, with local order, visible grain boundaries, and bluish color; and (iii) single or monocrystalline, which is typified by long-range order and periodicity and is almost black with no visible grain boundaries. Furthermore, the crystalline structure of a semiconductor is important because when a small concentration of impurities (other elements such as phosphorus or boron) are introduced into the structure, the conductive properties of the material can radically change.

Cells for terrestrial applications are typically made from silicon as single-crystal, polycrystalline, or amorphous solids. Single-crystal silicon is the most efficient because the crystal is free of grain boundaries, which are defects in the crystal structure caused by variations in the lattice that tend to decrease the electrical and thermal conductivity of the material. They can be thought of as barriers to electron flow. Polycrystalline silicon has obvious grain boundaries. The portions of single crystals are visible to the naked eye. Amorphous silicon (a-Si) is the noncrystalline form of silicon where the atoms are arranged in a relatively haphazard way. Due to the disordered nature of the material, some atoms have a dangling bond that disrupts the flow of electrons. A dangling bond occurs when an atom is missing a neighbor to which it would be able to bind. Amorphous silicon has lowest power conversion efficiencies of the three types, but is the least expensive to produce.

Monocrystalline Silicon

The cells are made from an ingot of a single crystal of silicon, grown in high-tech labs, sliced, then doped and etched. For commercial terrestrial modules, efficiencies typically range from approximately 15 to 20%. Modules made of this type of cell are the most mature on the market. Reliable manufacturers of this type of photovoltaic module offer guarantees of up to 20–25 years at 80% of nameplate rating.

Polycrystalline Silicon

The cells are made up of various silicon crystals formed from an ingot. They are also sliced and then doped and etched. They demonstrate conversion efficiencies slightly lower than those of monocrystalline cells, generally from 13 to 15%. Reliable manufacturers typically guarantee polycrystalline photovoltaic modules for 20 years.

Amorphous Silicon

The term *amorphous* refers to the lack of any geometric cell structure. Amorphous modules do not have the ordered pattern characteristic of crystals as in the case of crystalline silicon. Commercial modules typically have conversion efficiencies from 5 to 10%. Most product guarantees are for 10 years, depending on the manufacturer.

Amorphous materials have found wide appeal for use in consumer devices (e.g., watches and calculators). It does have the advantage for some grid-tied or water-pumping systems in that higher voltage modules can be produced more cheaply than their crystalline counterparts. Another limiting factor to efficiency is that of traps in the material. Traps are semiconductor material impurities in the depletion region and can greatly increase recombination of electrons and holes.

A photovoltaic array is a group of modules that are electrically connected either in series or in parallel. The electrical characteristics of the array are analogous to those of individual modules, with the power, current, and voltage modified according to the number of modules connected in series or parallel. Maximum energy is obtained when the Sun's rays strike the receiving surface perpendicularly. In the case of photovoltaic arrays, perpendicularity between the rays of the Sun and the modules can be achieved only if the structural mounting of the modules allows the structure to follow the movements of the Sun.

Energy storage for photovoltaic systems commonly consists of batteries to store and discharge electrical energy as needed. However, each time a battery is charged or discharged, some energy is lost from the system. Batteries vary by type, depth of discharge, rate of charge, and lifetime (in photovoltaic applications). The most common types of batteries used with photovoltaic systems are lead-acid, but other more exotic and expensive batteries are sometimes used, such as nickel metal hydride. A new area of photovoltaic battery applications is emerging in which the photovoltaic battery is used for backup power when the utility grid fails for grid-tied photovoltaic systems. This application has unique battery charging and maintenance requirements. Batteries are usually installed in well-ventilated locations such as garages, utility rooms, and outbuildings to minimize the potential for capturing explosive concentrations of hydrogen gas and to minimize possible hazards from electrolyte spills.

Environmental Impact

While the widespread use of photovoltaic cells will reduce global warming by helping to cut down on the use of electricity created by the combustion of fossil fuels, the manufacture of this solar technology can be polluting. Most manufacturers use mercury to construct solar cells – mercury is a toxic waste that must be disposed of during the manufacture of the cells as well as after the cells have reached the end of their usefulness.

Physical Solvent Processes

Physical solvent processes are processes that use a solvent to purify gas streams. Two of the currently most-widely-used physical solvent processes for gas cleaning are *Selexol* and *Rectisol* processes. The *Selexol* process solvent is the dimethyl ether of polyethylene glycol, while the *Rectisol* solvent is methanol.

The principal benefits of physical solvents are (i) high selectivity for hydrogen sulfide over carbonyl sulfide and carbon dioxide, (ii) high loadings at high acid gas partial pressures, (iii) stability of the solvent, and (iv) low heat requirements because most of the solvent can be regenerated by a simple pressure letdown.

The performance of a physical solvent can be easily predicted. The solubility of a compound in the solvent is directly proportional to its partial pressure in the gas phase, hence, the improvement in the performance of physical solvent processes with increasing gas pressure. Physical solvent processes can be easily configured to take advantage of their high hydrogen sulfide/carbon dioxide selectivity together with high levels of carbon dioxide recovery.

The Selexol process is a mixture of the dimethyl ethers of polyethylene glycol $[\text{CH}_3(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_3]$ where n is between 3 and 9. The solvent is chemically and thermally stable, and has a low vapor pressure that limits its losses to the treated gas. The solvent has a high solubility for carbon dioxide, hydrogen sulfide, and carbonyl sulfide. It also has appreciable selectivity for hydrogen sulfide over carbon dioxide.

The Selexol process can be configured in various ways, depending on the requirements for the level of hydrogen sulfide/carbon dioxide selectivity, the depth of sulfur removal, the need for bulk carbon dioxide removal, and whether the gas needs to be dehydrated. The gas stream from the low-pressure flash is combined with the acid gas from the regenerator. This combined gas stream is then sent to a sulfur recovery unit. However, the hydrogen sulfide content could be too low for use in a conventional Claus plant. However, the Selexol process can be configured to give a rich acid gas feed to the Claus unit as well as to provide for bulk carbon dioxide removal.

See also: Gas Cleaning, Claus Process, Selexol Process.

Physical Transformation Reactions

A physical conversion that is often ignored (or not recognized as such) is the change in composition that occurs when precipitation and dissolution reactions exert a major effect on the concentrations of inorganic ions in solution. Also included is the effect of adsorption and absorption on the composition of the pollutant.

The precipitation of a solid phase in environmental systems rarely results in a pure mineral phase. Minor elements such as cadmium can coprecipitate with major elements such as calcium to form a solid solution. In addition, the equilibrium activity of the component of a solid solution does not correspond to the solubility calculated from the solubility products of pure minerals. Furthermore, it is often impossible to distinguish chemically between a minor component coprecipitated in a solid, and the adsorption of that minor component onto the solids surface.

Also, complexation is an important process that will determine in some cases if mineral solubility limits are reached, the amount of adsorption that occurs, and the redox state that exists in the water. Inorganic chemicals can also form stable, soluble complexes with organic ligands. Ligands in leachates could include synthetic chelating agents (such as ethylenediamine), partially oxidized biodegradation products (such as organic acids), or natural humic materials. In fact, the movement of metals in the subsurface is strongly influenced by the concentration and chemical properties of ligands. However, the types and concentrations of ligands in most waste leachates is largely unknown.

Physical changes are changes affecting the form of an inorganic chemical but not always the chemical composition. Physical changes are used to separate mixtures into their component compounds, such as the use of liquid-solid chromatography, but cannot usually be used to separate compounds into chemical elements or simpler compounds. Thus, physical changes occur when objects or substances undergo a change that does not change their chemical composition. This contrasts with the concept of chemical change in which the composition of a substance changes or one or more chemicals combine or react (by combination or by degradation) to form new chemical products.

A common example that can be treated as a physical transformation is the settling of suspended sediment particles. Although settling does not actually transform the sediment into something else, it does remove sediment from the control volume by depositing it on the river bed. This process can be expressed mathematically by heterogeneous transformation equations at the river bed and can be considered to be a transformation process.

Another example of a physical change comes from the field of nuclear physics and is radioactive decay. Radioactive decay is the process by which an atomic nucleus emits particles or electromagnetic radiation to become either a different isotope of the same element or an atom of a different element. The three radioactive decay paths are alpha decay (the emission of a helium nucleus), beta decay (the emission of an electron or positron), and gamma decay (the emission of a photon). Gamma decay alone does not result in transformation, but it is generally accompanied by beta emission, which does.

More pertinent to the current text is the effect of sorption process and dilution on the properties of the contaminant.

Inorganic chemicals interact with the environment in different ways, and once a chemical is released into the environment, there are three physical effects that can influence the distribution of the chemicals: (i) absorption, (ii) adsorption, and (iii) dilution.

Physical Transformation Reactions – Absorption

Absorption is another phenomenon that can be a beneficial or adverse influence of the environment and involves the uptake of one chemical substance into the inner structure of another substance – most typically a gas into a liquid solvent. Furthermore, absorption is a physical or chemical phenomenon or a process in which atoms, molecules, or ions enter some bulk phase – gas, liquid, or solid material. This is a different process from *adsorption*, since molecules undergoing absorption are taken up by the volume, not by the surface (as in the case for adsorption). The process of absorption means that a substance captures and transforms energy and the absorbent distributes the material it captures throughout whole and adsorbent only distributes it through the surface.

In chemical absorption (sometimes referred to in the shortened word form as *chemisorption*), the absorbed material is generally converted to a product different to the starting material. Thus, chemical absorption or *reactive absorption* involves a chemical reaction between the absorbent (the absorbing substance) and the absorbate (the absorbed substance) and may be combined with the physical absorption phenomenon. This type of absorption depends upon the stoichiometry of the reaction and the concentration of the potential reactants.

Physical absorption or non-reactive absorption is made between two phases of matter: a liquid absorbs a gas, or a solid absorbs a liquid. When a liquid solvent absorbs a gas mixture or part of it, a mass of gas moves into the liquid. For example, water may absorb oxygen from the air. This mass transfer takes place at the interface between the liquid and the gas, at a rate depending on both the gas and the liquid. This type of absorption depends on the solubility of gases, the pressure, and the temperature. The rate and amount of absorption also depend on the surface area of the interface and its duration in time. For example, when the water is finely divided and mixed with air, as may happen in a waterfall or a strong ocean surf, the water absorbs more oxygen. When a solid absorbs a liquid mixture or part of it, a mass of liquid moves into the solid. This mass transfer takes place at the interface between the solid and the liquid, at a rate depending on both the solid and the liquid. Absorption is essentially a molecule attaching themselves to a substance and will not be attracted from other molecules.

On the other hand, chemical absorption or reactive absorption is a chemical reaction between the absorbed and the absorbing substances. Sometimes, it combines with physical absorption. This type of absorption depends upon the stoichiometry of the reaction and the concentration of its reactants.

See also: Absorption.

Physical Transformation Reactions – Adsorption

Adsorption is the physical accumulation of material (usually a gas or liquid) on the surface of a solid adsorbent and is a *surface phenomenon* (Calvet, 1989). Typically, adsorption processes remove solutes from liquids based on their mass transfer from liquids to porous solids. Ion exchange is the exchange of dissolved ions for ions on solid media. The process can be used to remove water hardness and toxic metals during wastewater treatment. Disinfection is the removal or inactivation of pathogenic organisms in wastewater prior to be discharged to the receiving body of water.

In nature, a variety of potential natural adsorbents exists in the soil – adsorption occurs in many natural, physical, biological, and chemical systems (especially in the environment) where inorganic molecules can adsorb on to minerals (such as clay) or on to charred wood that remains after a forest fire. In fact, clay minerals are particularly good adsorbents and have a high adsorption capacity for inorganic chemicals that have been released into the environment.

A natural clay mineral is not composed of one clay mineral only. Impurities such as calcite (CaCO_3), quartz (SiO_2), feldspar ($\text{KAlSi}_3\text{O}_8/\text{NaAlSi}_3\text{O}_8/\text{CaAl}_2\text{Si}_2\text{O}_8$), iron oxides, (FeO and Fe_2O_3) and humic acids (degradation products of organic materials) are the most common components in addition to the pure clay mineral. Calcite, iron oxides, and humic acids can be removed by chemical treatments. Quartz and feldspar can be removed by sedimentation if the particle size is bigger than that of the clay minerals, but traces of quartz are often found in the purified samples. Physically, clay minerals are typically ultrafine-grained [normally considered to be less than 2 micrometers (<2 microns, $<2 \times 10^{-6}$ meters) in size on standard particle size classifications]. In the present context, clay minerals,

which can be classified into various chemical groups, such as the silicate clay mineral groups are an important part of many soils, thus rendering the soil capable of having a high adsorption capacity for inorganic chemicals. Generally, no two clay minerals are the same and the adsorption capacity will vary accordingly.

Adsorption of an inorganic chemical on to a solid adsorbent, such as a clay mineral or any other mineral, is measured by a partition coefficient, which is the ratio of the concentration the inorganic chemical on the solid to the concentration of the chemical in the fluid (usually water) surrounding the solid:

$$K_d = C_{\text{solid}}/C_{\text{water}}$$

The concentration on the solid has units of mol/kg, and the concentration in the water is mol/L and, thus, the adsorption coefficient (K_d) has units of L/kg. Assuming a solid density of 1 kg/L, these units are often ignored. The adsorption coefficient will often depend on how much of the total mass of the particle is inorganic material. Thus, the adsorption coefficient can be corrected by the fraction of inorganic material (f_{om}) in the particles:

$$K_{\text{om}} = K_d/f_{\text{om}}$$

Adsorbed molecules are those that are resistant to washing with the same solvent medium in the case of adsorption from solutions. The washing conditions can thus modify the measurement results, particularly when the interaction energy is low. The exact nature of the bonding depends on the details of the chemical species involved, but the adsorption process is generally classified as physisorption (which is characteristic of weak van der Waals forces which can be attractive or repulsive) or chemisorption (which is characteristic of covalent bonding). It may also occur due to electrostatic attraction.

The ease of desorption of the inorganic is also an important consideration, because in the treatment of wastewaters, materials are used primarily as ion exchangers, while for *in situ* immobilization, the metals need to be irreversibly bound to the added adsorbent.

See also: Adsorption.

Physical Transformation Reactions – Dilution

Dilution is the process in which an inorganic chemical in an ecosystem becomes less concentrated and there is a decrease in the concentration of a solute in solution, usually simply by mixing with additional solvent (such as water). Dilution is also a reduction in the acidity or alkalinity of an inorganic chemical (gas, vapor, solution). To dilute a solution means to add more solvent without the addition of more solute. The resulting solution is thoroughly mixed to ensure that all parts of the solution are identical. Mathematically, dilution can be represented by a simple equation:

$$C_1 \times V_1 = C_2 \times V_2$$

In this equation, C_1 is the initial concentration of the solute, V_1 is the initial volume of the solution, C_2 is the final concentration of the solute, and V_2 is the final volume of the solution. However, this type of simple equation does not consider any solute-solvent interactions, solute-solute interactions, and solvent-solvent interactions.

Dilution of the chemical may reduce the risk to the floral and faunal species because the potential individual receptors are likely to be exposed to lower, less toxic concentrations of the hazard. However, the chronic effects associated with the dilution of a toxic inorganic chemical (or any chemical for that matter) to a less-concentrated form is extremely difficult to measure. By itself, however, dilution does not reduce the mass of the chemical but, rather, spreads the area of potential exposure to the chemical. In addition, some inorganic contaminants are believed hazardous (such as the always lethal potassium cyanide, KCN) even at levels that may be too dilute to be detected with standard field characterization equipment and techniques.

Physisorption

In contrast with chemisorption (chemical adsorption), physisorption (physical adsorption) is the phenomenon which leaves the chemical species of the adsorbate and surface intact. It is conventionally accepted that the energetic threshold separating the binding energy of physisorption from that of chemisorption is approximately 0.5 eV per adsorbed species.

Adsorption is the phenomenon marked by an increase in density of a fluid near the surface of a solid. In the case of gas adsorption, this happens when molecules of the gas occasion to the vicinity of the surface and undergo an interaction with it, temporarily departing from the gas phase. Molecules in this new condensed phase formed at the surface remain for a period of time, and then return to the gas phase. The duration of this stay depends on the nature of the adsorbing surface and the adsorptive gas, the number of gas molecules that strike the surface and their kinetic energy (or collectively, their temperature), and other factors (such as capillary forces, surface heterogeneities, etc.). Adsorption is by nature a surface phenomenon, governed by the unique properties of bulk materials that exist only at the surface due to bonding deficiencies.

Pile Burners

Pile burners consist of cells, each having an upper and a lower combustion chamber. Biomass fuel burns on a grate in the lower chamber, releasing volatile gases. The gases burn in the upper (secondary) combustion chamber, and pile burners must be shut down periodically to remove ash.

Pile burners represent the historic industrial method of wood combustion and typically consist of a two-stage combustion chamber with a separate furnace and boiler located above the secondary combustion chamber. The combustion chamber is separated into a lower pile section for primary combustion and an upper secondary-combustion section. Wood is piled approximately 3.3 m (10 ft) deep on a grate in the bottom section, and combustion air is fed upwards through the grate and inwards from the walls; combustion is completed in a secondary combustion zone using overfire air. The wood fuel is introduced either on top of the pile or through an underfeed arrangement using an auger. The underfeed arrangement gives better combustion control by introducing feed underneath the active combustion zone, but it increases system complexity and lowers reliability. Ash is removed by isolating the combustion chamber from the furnace and manually dumping the ash from the grate after the ash is cooled. Pile burners typically have low efficiencies (50% to 60%), have cyclic operating characteristics because of the ash removal, and have combustion cycles that are erratic and difficult to control. Because of the slow response time of the system and the cyclic nature of operation, pile burners are not considered for load-following operations. The advantage of the pile burner is its simplicity and ability to handle wet, dirty fuels.

See also: Combustion, Stoker Combustors.

Pipeline Corrosion

As in the fossil fuels industry, the transportation of gases and liquids (from alternative energy sources) by pipeline can cause corrosion to the pipeline. One of the common problems in multiphase flow transmission pipelines is metal corrosion. Corrosion is defined as the deterioration of material, usually a metal, due to its reaction with the environment or handling media. The cause of corrosion can be directly attributed to the impurities found in the produced gas, as well as the corrosive components that are by-produced. Because of the non-specificity of the components produced from a production well, some or all of these components may be active to create a corrosive environment in the pipelines.

Corrosion in multiphase systems is a complex phenomenon, including dependency on the partial pressure, temperature, pH, and concentration of corrosion products. Consequently, corrosion prediction requires substantial understanding of the simultaneous interaction of the many process variables that govern both flow and corrosion conditions.

An important aspect of maintaining pipeline performance is adequate control of corrosion both internally (caused by the flow components and their by-products) and externally (because of pipeline exposure to the soil and water). Pipeline corrosion can be inhibited by several means which are (i) the choice of corrosion-resistant metals, alloys, (ii) the injection of corrosion inhibitors, (iii) cathodic protection, and (iv) the use of external and/or internal protective coatings.

While corrosion control can be achieved by selection of an appropriate corrosion-resistant metal, operating considerations usually dictate that a high-efficiency corrosion control system be used. Protecting pipelines from corrosion is achieved internally by the injection of inhibitors to mitigate internal corrosion and externally by use of cathodic protection and/or a combination of coatings and cathodic protection (for buried or subsea pipelines).

See also: Pipeline Protective Coating, Pipeline Transportation.

Pipeline – Protective Coating

While cathodic protection has historically been employed as the sole corrosion control methodology for subsea gas production systems, the nature of multiphase pipelines is such that the combined use of protective coatings with cathodic protection is necessary to achieve the effective protection. In fact, protective coatings help control pipeline corrosion by providing a barrier against reactants such as oxygen and water. However, because all organic coatings are semipermeable to oxygen and water, coatings alone cannot prevent corrosion and so a combination of cathodic protection is often used.

Pipelines are often internally coated to minimize corrosion when lying in pipeline dumps prior to construction and to provide a smooth surface that reduces friction when fluids are in transit. It should be noted that the initial period in the life of a production well can be its most corrosive time due to the high partial pressure of the carbon dioxide. Therefore, it may be more economical to protect the multiphase pipelines from a young field.

The coating must be compatible with the commodity and should have suitable resistance to attack by the commodity as well as any contaminants, corrosives, or inhibitor associated with it. Coatings such as epoxies, plastics, or metallic compounds can be used for selected applications. The oldest and still used approach consists of hot-applied bituminous material wrapped with an appropriate covering. External coatings are used to reduce the value of the external current to an economic level by imposing a barrier of high electrical resistance between metal and its environment.

Pipelines are susceptible to both internal and external corrosion. Therefore, both internal and external monitoring of a pipeline are required for a complete assessment, thus providing the direction that will ensure proper utilization of materials and corrosion control methodologies. While traditional inspection and monitoring techniques may represent effective solutions for assessment of the condition and integrity of a pipeline, the sensitivity and accuracy of these methods may be inadequate for monitoring inhibitor performance. However, the field signature method (FSM) continuously monitors corrosion taking place at a given point on the subsea pipeline and remaining pipe wall thickness at any time. This information can be transferred immediately to the surface, allowing the operator to take immediate action. Compared with traditional corrosion monitoring methods, the FSM reduces costs, improves safety, and may reduce the required frequency of intelligent pigging. The method requires virtually no maintenance or replacement of consumables. Its service life equals that of the pipe itself. However, it is still a relatively new technique and experience is improving.

See also: Pipeline Corrosion, Pipeline Transportation.

Pipeline Transportation

Pipelines are a very convenient method of transport but are not flexible as the gas will leave the source and arrive at its (one) destination. Once the pipeline diameter is decided, the quantities of gas that can be delivered are fixed by the pressures, although an increase in the maximum quantity can be achieved by adding compressors along the line, extra pipe in the form of loops, or by increasing the average pipeline pressure. However, if the pipeline has to be shut

down, the production and receiving facilities, be it gas reservoir, processor, or refinery, often also have to be shut down because gas cannot be readily stored, except perhaps by increasing the pipeline pressure by some percentage.

Pipeline pressures (onshore) usually operate under pressure at 700 to 1,100 psi (although 4,000 psi lines are in operation), and offshore pipelines operate under pressures on the order of 1,400 to 2,100 psi. The pressure does depend on the material of construction and the age of the pipe, and the high operating pressure reduces the volume of the natural gas being transported (by up to 600 times), as well as providing propellant force to move the natural gas through the pipeline. Pipeline installation costs vary but generally cost several million dollars (US) per mile depending on the terrain plus compressor stations. Sub-sea lines over 2,000 miles have, until recently, been regarded as uneconomic, because of the sub-sea terrain making pipeline installation and maintenance expensive and any recompression along the route difficult, but changes are in the air!

To ensure that the natural gas flowing through any one pipeline remains pressurized, compression of this natural gas is required periodically along the pipe. This is accomplished by compressor stations, usually placed at 40 to 100 mile intervals along the pipeline. The natural gas enters the compressor station, where it is compressed by a turbine, a motor, or an engine.

Turbine compressors gain their energy by using up a small proportion of the natural gas that they compress. The turbine itself serves to operate a centrifugal compressor, which contains a type of fan that compresses and pumps the natural gas through the pipeline. Some compressor stations are operated by using an electric motor to turn the same type of centrifugal compressor. This type of compression does not require the use of any of the natural gas from the pipe, but it does require a reliable source of electricity nearby. Reciprocating natural gas engines are also used to power some compressor stations. These engines resemble a large automobile engine, and are powered by natural gas from the pipeline. The combustion of the gas powers pistons on the outside of the engine, which serves to compress the natural gas.

In addition to compressing natural gas, compressor stations also usually contain some type of liquid separator, much like the ones used to dehydrate natural gas during its processing. Usually, these separators consist of scrubbers and filters that capture any liquids or other undesirable particles from the natural gas in the pipeline. Although natural gas in pipelines is considered to be *dry gas*, it is not uncommon for a certain amount of water and hydrocarbon derivatives to condense out of the gas stream while in transit. The liquid separators at compressor stations ensure that the natural gas in the pipeline is as pure as possible, and usually filters the gas prior to compression.

In addition to compressing natural gas to reduce its volume and push it through the pipe, metering stations are placed periodically along interstate natural gas pipelines. These stations allow pipeline companies to monitor and manage the natural gas in their pipes. The metering stations measure the flow of gas along the pipeline, and allow pipeline companies to monitor the natural gas as it flows along the pipeline. These metering stations employ specialized meters to measure the natural gas as it flows through the pipeline, without impeding its movement.

In the United States, there are essentially three major types of pipelines along the transportation route which are (i) the gathering system, (ii) the interstate pipeline, and (iii) the distribution system. The gathering system consists of low-pressure, low-diameter pipelines that transport raw natural gas from the wellhead to the processing plant. If natural gas from a particular well has a high sulfur content and a high carbon dioxide content (sour gas), a specialized sour gas gathering pipe must be installed. Sour gas is extremely corrosive and dangerous, thus its transportation from the wellhead to the sweetening plant must be done carefully.

In the United States, pipelines can also be characterized as interstate or intrastate. Interstate pipelines carry natural gas across state boundaries, in some cases clear across the country. Intrastate pipelines, on the other hand, transport natural gas within a particular state. In addition, natural gas pipelines are subject to regulatory oversight, which in many ways determines the manner in which pipeline companies must operate. The interstate natural gas pipeline network transports processed natural gas from processing plants in producing regions to those areas throughout the country with high natural gas requirements, particularly large, populated urban areas.

Interstate pipelines carry natural gas across state boundaries, in some cases clear across the country. Intrastate pipelines, on the other hand, transport natural gas within a particular state. In addition, natural gas pipelines are subject to regulatory oversight, which in many ways determines the manner in which pipeline companies must operate. Pitch

Pitch is the nonvolatile, brown-to-black, semi-solid-to-solid viscous product from the destructive distillation of many bituminous materials or other organic materials (such as coal). It is also the name that is given (incorrectly) in the crude oil refining industry to the atmospheric residuum (atmospheric pitch) and vacuum residuum (vacuum pitch). The term should be carefully explained whenever it is in use.

On a scientific basis, pitch is considered to be a viscoelastic polymer which can be natural or manufactured, derived from crude oil, tar sand, or plant species. Various forms of pitch may also be called (incorrectly) tar, bitumen, or asphalt – in the refining industry, the vacuum residuum or the non-volatile material from various reactors (e.g., deasphalter pitch) is often referred to as pitch. Pitch produced from plants is also known as resin, and some products made from plant resin are also known as rosin.

Pitch was traditionally used to caulk the seams of wooden sailing vessels and to coat earthenware vessels for the preservation of liquids, such as wine. Pitch may also be used to waterproof wooden containers and in the making of torches. Crude oil-derived pitch is black in color, hence the adjectival phrase, pitch-black.

In the present context, pitch from any source can be subjected to pyrolysis to produce an array of products that fall into three categories: (i) gases, (ii) liquids, and (iii) solids. Also, heating (dry distillation, pyrolysis with simultaneous removal of distillate) of wood produces tar (the volatile constituents) and pitch (the non-volatile constituents) – the pitch is eventually decomposed further to produce char or charcoal.

While the terms tar and pitch are often used interchangeably – as indicated above – tar is more liquid and the volatile product of thermal decomposition, while pitch is considered a more non-volatile (often solid) distillation residue. Either tar or pitch can be decomposed further to produce fuel products.

Plant Fibers

Plant fibers (lignocellulosic fibers) are extracted from plants such as hemp and flax can replace cotton and polyester fibers in textile materials and glass fibers in insulation products.

Natural fibers can be classified according to their origin, thus: (i) the vegetable, or cellulose-base, class includes such important fibers as cotton, flax, and jute and (ii) the animal, or protein-base, fibers include wool, mohair, and silk.

The vegetable fibers can be divided into smaller groups based on their origin within the plant. Chemically, all vegetable fibers consist mainly of cellulose with varying amounts of such substances as pectin, hemicellulose, and lignin. Pectin is a structural acidic heteropolysaccharide contained in the cell walls of terrestrial plants – the main component of pectin is galacturonic acid, a sugar derived from galactose.

With the exception of mineral fibers, all natural fibers have an affinity for water in both liquid and vapor form. This strong affinity produces swelling of the fibers connected with the uptake of water, which facilitates dyeing in aqueous solutions.

See also: Biomass.

Plasma

The word *plasma* is used to describe a wide variety of macroscopically neutral substances containing many interacting free electrons and ionized atoms or molecules, which exhibit collective behavior due to the long-range coulomb forces. Not all media containing charged particles, however, can be classified as plasmas. For a collection of interacting charged and neutral particles to exhibit plasma behavior, it must satisfy certain conditions, or *criteria*, for plasma existence.

Matter is often classified in terms of four states: (i) gaseous, (ii) liquid, (iii) solid, and (iv) plasma. The basic distinction among the three common states of matter (gaseous, liquids, and solids) lies in the difference between the strength of the bonds that hold their constituent particles together. These binding forces are relatively strong in a

solid, weak in a liquid, and essentially almost absent in the gaseous state. Whether a given substance is found in one of these states depends on the *random kinetic energy* (thermal energy) of its atoms or molecules, i.e., on its temperature. The equilibrium between this particle thermal energy and the interparticle binding forces determines the state.

By heating a liquid or solid substance, the atoms or molecules acquire more thermal kinetic energy until they are able to overcome the binding potential energy. This leads to *phase transitions*, which occur at a constant temperature for a given pressure. The amount of energy required for the phase transition is called the *latent heat*.

If sufficient energy is provided, a molecular gas will gradually dissociate into an atomic gas as a result of collisions between those particles whose thermal kinetic energy exceeds the molecular binding energy. At sufficiently elevated temperatures, an increasing fraction of the atoms will possess enough kinetic energy to overcome, by collisions, the binding energy of the outermost orbital electrons, and an *ionized gas* or *plasma* results. However, this transition from a gas to a plasma is not a phase transition in the thermodynamic sense since it occurs gradually with increasing temperature.

See also: Plasma Arc Technology, Plasma Production.

Plasma Arc Technology

Plasma arc technology is a heating method that can be used in both pyrolysis and gasification systems. This technology was developed for the metals industry in the late nineteenth century.

Plasma arc technology uses high temperatures to break down the feedstock into elemental by-products. Plasma arc devices (plasma torches) can be one of two types: the transferred torch, and the non-transferred torch.

The transferred torch creates an electric field between an electrode (the tip of the torch) and the reactor wall or conducting slag bath. When the field strength is sufficiently high, an electric arc is created between the electrode and reactor (much like an automotive spark plug). The non-transferred torch creates the electric arc internal to the torch and sends a process gas (such as air or nitrogen) through the arc, where it is heated, and then leaves the torch as a hot gas. High temperatures are created in the ionized plasma (the plasma can reach temperatures of 3,875°C (7,000°F) and above; the non-ionized gases in the reactor chamber can reach 925 to 1,205°C (1,700 to 2,200°F), and the molten slag is typically around 1,650°C, 3,000°F).

See also: Plasma, Pyrolysis.

Plasma Gasifier

Plasma gasification is an extreme thermal process using plasma which converts organic matter into synthesis gas – primarily a mixture of hydrogen and carbon monoxide with slag remaining as a by-product. A plasma torch powered by an electric arc is used to ionize gas and is used commercially as a form of waste treatment as well as it has been tested for the gasification of biomass, industrial waste, refuse-derived fuel, and hazardous waste.

The high temperature and lack of oxygen prevents the formation of many toxic compounds such as furan derivatives, dioxin derivatives, nitrogen oxides, or sulfur dioxide in the flame itself. However, dioxin derivatives can be formed when the synthesis gas is cooled. A portion of the synthesis gas produced can be used as a feed to on-site turbines, which power the plasma torches and thus support the feed system.

Metals resulting from plasma pyrolysis can be recovered from the slag and eventually sold as a commodity. Inert slag produced from some processes is granulated and can be used in construction.

Plasma Production

A plasma can be produced by raising the temperature of a substance until a reasonably high fractional ionization is obtained. Under thermodynamic equilibrium conditions, the degree of ionization and the electron temperature are closely related. Plasmas in local thermodynamic equilibrium are found in many places in nature, as is the case for many astrophysical plasmas.

Plasmas can also be generated by ionization processes that raise the degree of ionization much above its thermal equilibrium value. There are many different methods of creating plasmas in the laboratory and, depending on the method, the plasma may have a high or low density, high or low temperature, it may be steady or transient, stable or unstable, and so on. In what follows, a brief description is presented of the most commonly known processes of *photoionization* and *electric discharge* in gases.

In the *photoionization* process, ionization occurs by absorption of incident photons whose energy is equal to, or greater than, the ionization potential of the absorbing atom. The excess energy of the photon is transformed into

kinetic energy of the electron-ion pair formed. For example, the ionization potential energy for the outermost electron of atomic oxygen is 13.6 eV, which can be supplied by radiation of wavelength smaller than approximately 91 nm, i.e., in the far ultraviolet. Ionization can also be produced by x-rays or gamma rays, which have much smaller wavelengths. The ionosphere of the Earth, for example, is a natural photoionized plasma.

In a *gas discharge*, an electric field is applied across the ionized gas, which accelerates the free electrons to energies sufficiently high to ionize other atoms by collisions. One characteristic of this process is that the applied electric field transfers energy much more efficiently to the light electrons than to the relatively heavy ions. The electron temperature in gas discharges is therefore higher than the ion temperature since the transfer of thermal energy from the electrons to the heavier particles is slow.

When the ionizing source is turned off, the ionization decreases gradually because of recombination until it reaches an equilibrium value consistent with the temperature of the medium. In the laboratory, the recombination usually occurs so fast that the plasma completely disappears in a small fraction of a second.

Plasma Torch

A plasma torch (also known as a plasma arc, plasma gun, plasma cutter, or plasmatron) is a device for generating a directed flow of plasma which can be used for applications including plasma cutting, plasma arc welding, plasma spraying, and plasma gasification for waste disposal.

Thermal plasmas are generated in plasma torches by direct current (DC), alternating current (AC), radio frequency (RF), and other discharges. Direct current torches are the most commonly used and researched, because when compared to alternating current torches, the direct current torches offer (i) a more stable operation, (ii) better control, (iii) a minimum of two electrodes, (iv) lower electrode consumption, (v) slightly lower refractory wear, and (vi) lower power consumption.

In a direct current torch, the electric arc is formed between the electrodes (which can be made of materials such as copper, tungsten, graphite, and silver), and the thermal plasma is formed from the continual input of carrier/working gas, projecting outward as a plasma jet/flame (as can be seen in the adjacent image). Also, in direct current torches, the carrier gas can be, for example, either oxygen, nitrogen, argon, helium, air, or hydrogen and although termed such, it does not have to be a gas (thus, better termed a carrier fluid). However, the electrode materials and carrier fluids have to be specifically matched to avoid excessive electrode corrosion or oxidation (and contamination of materials to be treated), while maintaining ample power and function. Furthermore, the flow-rate of the carrier gas can be raised to promote a larger, more projecting plasma jet, provided that the arc current is sufficiently increased, and vice versa.

Platform Chemicals

There are a number of potential platform chemicals that can be produced from agricultural feedstocks, including: citric acid, lactic acid, levulinic acid, succinic acid, and 1,3-propanediol, to name some of the more commonly discussed platforms. Each of these platforms has created interest in Europe and North America.

In the long term, North American industry intends to focus on using cheap lignocellulosic wastes to make sugars, which can be used as a platform for deriving various biochemical products. Under this scenario, three key factors must be present for the production of platform chemicals to be economically viable: access to large amounts of cheap lignocellulosic feedstocks; a ten-fold reduction in enzyme costs; and access to an existing ethanol and/or starch processing infrastructure that can act as a bridge for the production of other chemicals.

The development of biorefinery technology and the use of renewable resources are gaining importance in the chemical industry. The emphasis lies in the production of platform chemicals and synthesis gas from biomass (lignocellulosic feedstock).

Biomass as a renewable feedstock offers the opportunity to replace fossil feedstocks as a source of energy, materials, and chemicals. Sugars, oils, and other compounds in biomass can be converted into platform chemicals directly or as by-products from fuel product in processes analogous to the petrochemical industry.

Examples of these platform chemicals are ethanol (C2), glycerol (C3), fumaric acid (C4), xylitol (C5), and sorbitol (C6). These building block chemicals have a high transformation potential into new families of useful molecules. The use of biomass-derived chemicals represents an area with the potential for the development of a renewable feedstock-based technology platform. Improvements and innovations to existing biological and chemical processing of sugars will provide the opportunity for the production of high-value chemicals and products from biomass and reduced reliance on petrochemical-derived products.

Plug Flow Digester

Anaerobic digestion is a series of processes in which microorganisms break down biodegradable material in the absence of oxygen, used for industrial or domestic purposes to manage waste and/or to release energy.

Plug-flow digesters are suitable for ruminant animal manure that has a solids concentration of 11% to 13%. A typical design for a plug-flow system includes a manure collection system, a mixing pit, and the digester itself. In the mixing pit, the addition of water adjusts the proportion of solids in the manure slurry to the optimal consistency. The digester is a long, rectangular container, usually built below-grade, with an airtight, expandable cover.

New material added to the tank at one end pushes older material to the opposite end. Coarse solids in ruminant manure form a viscous material as they are digested, limiting solids separation in the digester tank. As a result, the material flows through the tank in a plug.

The average retention time (the time a manure plug remains in the digester) is 20 to 30 days. Anaerobic digestion of the manure slurry releases biogas as the material flows through the digester. A flexible, impermeable cover on the digester traps the gas. Pipes beneath the cover carry the biogas from the digester to an engine-generator set.

A plug-flow digester requires minimal maintenance. Waste heat from the engine-generator can be used to heat the digester. Inside the digester, suspended heating pipes allow hot water to circulate. The hot water heats the digester to keep the slurry at 25°C to 40°C (77°F to 104°F), a temperature range suitable for methane-producing bacteria. The hot water can come from recovered waste heat from an engine generator fueled with digester gas or from burning digester gas directly in a boiler.

Plutonium

Plutonium is an element that can be easily split to generate large amounts of energy, quickly and, therefore, is valuable as a fuel for nuclear reactors and as a key ingredient for nuclear weapons.

Plutonium is a heavy metallic element (more than twice as dense as iron). Its freshly prepared, uncorroded surface has a bright, silvery appearance, which tarnishes rapidly when exposed to air. While most metals are good conductors of electricity and heat, plutonium is not. Its electrical conductivity (ability to conduct electricity) and its thermal conductivity (ability to conduct heat) are both exceptionally low, only approximately one-hundredth as much as the conductivities of silver. The principal radiation from plutonium is the alpha particle. Alpha radiation is totally stopped by a single sheet of paper or even an inch of air. These alpha particles cannot penetrate the outer layer of one's skin. Therefore, plutonium outside the body is considered harmless. Even ingestion of these materials is of relatively low risk to humans. The greatest risk is in inhaling plutonium particles.

Plutonium is a radioactive element with an atomic number 94, and its position in the Periodic Table of the Elements (Table p-2) shows that it is the sixth member in the series of elements called the "actinides," of which actinium, atomic number 89, is the first member. Plutonium is also one of the transuranium elements, since it has an atomic number higher than that of uranium (number 92). Element 93 and those with higher numbers are man-made by transmutation (changing one element into another).

Plutonium has 15 known isotopes which range in atomic weight from plutonium-232 to plutonium-246 (²³²Pu to ²⁴⁶Pu). All of the isotopes are radioactive and decay spontaneously, according to various sequences, eventually forming a stable element such as bismuth or lead. Although all the plutonium isotopes are the same chemically, the rates

at which they disintegrate radioactively differ widely. The half-life of the plutonium-233 (^{233}Pu) isotope, for example, is approximately 20 minutes, while that of the plutonium-244 (^{244}Pu) isotope is approximately 76 million years. At present, plutonium-239 is the isotope of greatest importance because it is readily fissionable, has the relatively long half-life of 24,360 years, and can be produced in amounts large enough to be of practical use. The fissionable property of plutonium makes it an important source of nuclear energy. When a neutron strikes the nucleus of a plutonium-239 (^{239}Pu) atom and sticks to it (rather than glancing off), the nucleus splits (or fissions) to form two atoms of different elements, each having an atomic number approximately half that of plutonium – strontium and xenon or barium and krypton are examples. At the same time, two or more neutrons are ejected from the plutonium nucleus.

The fissionable property of plutonium makes it an important source of nuclear energy. When a neutron strikes the nucleus of a plutonium-239 atom and sticks to it (rather than glancing off), the nucleus splits (or fissions) to form two atoms of different elements, each having an atomic number approximately half that of plutonium. (Strontium and xenon or barium and krypton are examples.) At the same time, two or more neutrons are ejected from the plutonium nucleus.

These new neutrons may be absorbed by nuclei of other plutonium atoms, which then fission, in turn, and emit more neutrons. A nuclear chain reaction of rapidly increasing intensity is thus started and will continue until all the plutonium atoms are used up or until the neutrons are prevented from reacting with the plutonium atoms by being trapped in some other material or by escaping. During the fission process, an enormous amount of energy in the form of heat is released. This energy is equivalent to the difference between the mass of the reactants and the mass of the products of the reaction. In this instance, the reactants are the plutonium atom and a neutron, and the products are the two newly produced elements of lower atomic number and the newly produced neutrons.

See also: Periodic Table of the Elements.

Polar Cell

The polar cell is similar to the Hadley in that at about 60° , there is rising motion and movement toward the pole at upper levels with westerly motion. There is a subpolar low pressure system where storms and clouds develop. The air sinks at the poles producing the polar high, and at the surface, there is deflection to cause polar easterlies as the air moves from poles to the sub-polar low. A polar front separates cold air coming from the poles from milder air coming from midlatitudes, and the peaks of precipitation in the mid-latitudes are primarily produced by extra-tropical cyclones that develop along this front.

However, the smallest and weakest cells are the Polar Cells, which extend from between 60 and 70 degrees north and south, to the poles. Air in these cells sinks over the highest latitudes and flows out toward the lower latitudes at the surface.

It is important to recognize the existence of two separate planetary-scale circumpolar vortices: one in the stratosphere and the other troposphere. These vortices have different structure, seasonality, dynamics, and impacts on extreme weather. The tropospheric vortex is much larger than its stratospheric counterpart and exists year-round, whereas the stratospheric polar vortex forms in fall but disappears in the spring of each year. Both vortices can, in some circumstances, play a role in extreme weather events at the surface, such as cold air outbreaks, but these events are not the consequence of either the existence or gross properties of these two vortices. Rather, cold air outbreaks are most related to transient, localized displacements of the edge of the tropospheric polar vortex which may, in some circumstances, be related to the stratospheric polar vortex: but there is no known one-to-one connection between these phenomena.

Pollutant

A pollutant is a substance or energy introduced into the environment that has undesired effects, or adversely affects the usefulness of a resource. A pollutant may cause long- or short-term damage by changing the growth rate of plant or animal species, or by interfering with human amenities, comfort, health, or property values. Some pollutants are biodegradable and therefore will not persist in the environment in the long term but can still cause damage to the environment during the lifetime of the pollutant. A pollutant can also be a naturally-occurring material that is reintroduced into the environment in an amount that exceeds the naturally occurring amount in the environment.

Following from this definition, a primary pollutant is a pollutant that is emitted directly from a source. On the other hands, a secondary pollutant is a pollutant that is produced by interaction of a primary pollutant and with another chemical or by dissociation of a primary pollutant or other effects within a particular ecosystem (Table P-6).

Table P-6 Typical environmental pollutants.*

Pollutant	Description
Mercury (Hg)	A chemical element commonly known as quicksilver, a liquid under STP**.
Ozone (O ₃)	A pale blue gas with a distinctively pungent smell; formed from oxygen by the action of ultraviolet (UV) light and electrical discharges (lightning) within the atmosphere of the Earth; present in low concentrations throughout the atmosphere; the highest concentration is in the ozone layer of the stratosphere.
Particulate matter (PM)	Microscopic particles of solid or liquid matter suspended in the air; sources can be natural or anthropogenic.
Persistent organic chemicals (POPs)	Organic compounds that are resistant to environmental degradation by chemical, biological, and photolytic processes.
PAHs	Chemical compounds containing only carbon and hydrogen in the form of multiple fused aromatic rings; the simplest such chemicals are naphthalene and phenanthrene, having two fused aromatic rings, and the three fused aromatic rings, respectively.
VOCs****	Organic compounds that have a high vapor pressure at room temperature; the high vapor pressure results from a low boiling point, which causes large numbers of molecules to evaporate (passes from liquid to gas) or sublimates (passes from solid to gas) and enter the surrounding air – often expressed as volatility.

*Listed alphabetically rather than by effect.

**Standard condition of temperature and pressure.

*** Polycyclic aromatic hydrocarbon derivatives; sometimes referred to as polynuclear aromatic hydrocarbon derivatives (PNAs).

****Volatile organic compounds

Human activities have released a large number of chemicals in the environment from industrial activities and domestic activities that are detrimental for health when they come into contact with human body. Many of these chemicals are toxic in nature and cause serious health problems in humans. Carcinogenic chemicals cause cancer where as many others cause various types of allergies in skin and respiratory system. Pesticides and a host of other chemicals enter the food chain through which it reaches human body and affects it adversely. Metals such as lead, mercury, and arsenic are introduced into the environment by industrial and domestics. These substances are toxic and cause various ailments when they enter the human body along with food or water.

For many pollutants, the atmosphere, the aquasphere, and the geosphere have the ability to sanitize (clean) themselves within hours or days, especially when the effects of the pollutant are minimized by the natural constituents of the ecosystem. For example, the atmosphere might be considered to be self-cleaning as a result of rain. However, removal of some pollutants from the atmosphere (such as sulfate derivatives and nitrate derivatives) by rainfall results in the formation of acid rain which can and will cause serious environmental damage to ecosystems within the aquasphere and the geosphere.

As a further aspect of this definition, the pollutant, by virtue of its name, has a detrimental effect on the environment, in part or in toto. Pollutants can also be subdivided into two classes which are (i) primary pollutants, and (ii) secondary pollutants:

Source → Primary pollutant → Secondary pollutant

Thus, a pollutant is a chemical which is emitted directly from the sources. In terms of atmospheric pollutants, the examples are carbon monoxide, carbon dioxide, sulfur dioxide (from which sulfur trioxide – in this case, a secondary pollutant is derived), and nitrogen oxides from combustion of carbonaceous fuels:

On the other hand, secondary pollutants are produced by the interaction of primary pollutants with another chemical or by the dissociation of a primary pollutant, or other effects within a particular ecosystem. Again, using the atmosphere as the example, the formation of the constituents of acid rain is an example of the formation of secondary pollutants:

In many cases, these secondary pollutants can have significant environmental effects, such as the formation of acid rain and smog.

Adsorption

The types of non-clay minerals and clays minerals in the soil give it the adsorption properties that are less desirable because of the ability of these minerals to trap potential pollutants within the soil.

Toxic substances including heavy metal(loid)s, such as arsenic (As), mercury (Hg), lead (Pb), cadmium (Cd), and chromium(VI) [Cr(VI)] and organic contaminants, such as polycyclic aromatic hydrocarbons (PAHs) (e.g., benzo[a]pyrene), persistent organic pollutants (POPs) (e.g., polychlorinated biphenyl) or emerging pollutants (e.g., per- and poly-fluoroalkyl substances, polybrominated biphenyls, etc. that present unique issues and challenges to environmental quality) have been detected in soils.

The adsorption and desorption of chemical pollutants in soils largely depend on (i) the type of mineral, (ii) the presence or absence of clay minerals, (iii) the pH, (iv) the redox conditions, and (v) the available chemical species. Inorganic ions, such as phosphate derivatives, HPO_4^{2-} , nitrate derivatives, NO_3^- , chloride derivatives, Cl^- , and sulfate derivatives, SO_4^{2-} and organic ligands, such as citrate, oxalate, fulvic, and dissolved organic carbon (DOC) can affect pollutant behavior in soils. Inorganic ions can influence adsorption through their interactions with metal(loid)s. For example, metal(loid)s complexed with such ions exhibit less sorption affinity to soils than free ions, but the free states of some ions (such as phosphate ions, PO_4^{3-}) in soil increase the net negative surface charge and therefore increase the sorption of cationic metal(loid)s. Soil organic constituents, such as soil organic matter, which is often estimated and expressed as soil organic carbon, play an important role in the sorption of soil pollutants. Some soil organic matter, such as humic substances, have a high affinity for metal cations. The heavy metal ion-binding ability of humic substances is attributed to the negative surface charge, particle size, and diffusion coefficient of humic acid as well as the content of oxygen-containing functional groups, including hydroxyl derivatives ($-\text{OH}$), carboxylic acid derivatives ($-\text{COOH}$), thiol derivatives ($-\text{SH}$), and aldehyde derivatives or ketone derivatives ($-\text{C}=\text{O}$). Another important process in soil is the microbial activity relative to the fate and transformation of pollutants. For example, the microbial degradation of hydrocarbon derivatives is experienced as the natural clean-up process of organic pollutants. Also, heavy metal(loid)s can be remediated using soil-grown plants (commonly accepted as phytoremediation), particularly with the microbial-assisted rhizosphere.

Organic pollutants can reach the soil either by purpose, such as pesticides and other agricultural chemicals, or incidentally through a variety of materials commonly used in agricultural practices, e.g., fertilizers and amendments. Once on the soil surface, the organic pollutant can be partially photo-decomposed and/or volatilized, and partially enter the soil or be transported to surface aquatic bodies by runoff and/or erosion. When in the soil, the pollutant can be subjected to partial or total chemical decomposition and/or biodegradation. The original pollutant and, possibly, its breakdown products may be adsorbed to soil organic and inorganic constituents, taken up by plant roots, and/or leached through the unsaturated zone eventually reaching the groundwater. All these processes are controlled by several factors including the physical and chemical properties of the pollutant and its breakdown products, the nature and thickness of the soil, the amount of water applied to the soil, and the type and extent of interactions between the pollutant and soil components.

The comment is often made that soil texture influences contaminant sorption phenomena and remediation processes in thermal desorption treatment. Also, contaminant removal was affected by soil texture. Although a soil could be all sand, all clay, or all silt, which is rare. Instead, most soils are a combination of the three. A clay loam texture soil, for example, has nearly equal parts of sand, silt, and clay and a soil with 15% w/w clay, 20% w/w silt, and 65% w/w sand has a sandy loam texture. Thus, soil texture is based on the relative proportions of each constituents in the soil of which non-clay minerals and clay minerals play important roles. In fact, the chemical and physical properties of a soil are related to texture. Particle size and distribution will also affect a capacity of the soil for holding water and nutrients. Fine-textured soils generally have a higher capacity for water retention, whereas sandy soils contain large pore spaces that allow leaching.

Thus, in order to determine the soil texture and to estimate the absorptive capacity of the soil, it is essential to know the constituents of the soil in terms of the amount of non-clay minerals (such as sand and silt) and the clay minerals (clay and often the amount of silt – silt can be fine sand, clay, or other material carried by running water and deposited as a sediment) in terms of the %w/w of sand, % w/w silt, and % w/w clay in the soil which can be estimated from the non-clay mineral and clay mineral content. However, this simplified approach to determining texture will may not have the required accuracy because of the ranges of the constituents and

if the soil contains a high amount of gypsum (CaSO_4) – soils that contain high amounts of gypsum (CaSO_4) typically show a pinkish-white hue. A more accurate test method (ASTM D7928) may be necessary using the soil triangle which is a diagram that illustrates how soils can be classified based on the percent of sand, silt, and clay in each.

Pollutant – Persistent

A persistent pollutant, like any chemical pollutant, can enter an ecosystem through the gas phase, the liquid phase, or solid phase and which can resist degradation and are mobile over considerable distances (especially in the gas phase or through transportation in river systems) before being re-deposited in a location that is remote to the location of their introduction into the ecosystem. Furthermore, pollutants can arise from various sources and can be present as vapors in the atmosphere or bound to (adsorbed on) the surface of soil or mineral particles and also have variable solubility in water.

Many persistent pollutants are currently (or were in the past) arose from the extensive use of fuels (from a variety of non-renewable and renewable sources) as well of agrochemicals (agricultural chemicals) such as pesticides, herbicides, and biocides, solvents, pharmaceuticals, and various industrial chemicals. Although some persistent pollutants arise naturally, for example from various biosynthetic pathways, most are products of human industry and tend to have higher concentrations and are eliminated more slowly. If not removed and because of their properties, persistent pollutants will bioaccumulate and have significant impacts on the flora and fauna of the environment. The most frequently used measure of the potential for bioaccumulations and the persistence of a compound in the environment are the result of the physicochemical properties (such as partition coefficients and reaction rate constants).

Solubility

From whatever the source of energy, chemicals are the most common type of contaminant in the aquasphere and they affect both surface and underground water bodies. Solvents and metals used in industries can pollute rivers and lakes. Weeds, insects, and fungi control in farms using pesticides is the other cause of soil contamination. The amount and dispersion of pollutants in the aquasphere is dependent upon the solubility of the pollutant in the water or the miscibility of the pollutant with water. In fact, many pollutants, through terrestrial runoff, direct discharge, or atmospheric deposition, end up in surface waters. In turn, rivers carry many of these pollutants to the sea. However, water quality varies from one location to the next depending on local geology, climate, biological activity, and human impact.

Even though nutrients are essential for plant and aquatic life, an excess of it is dangerous. Wastewater and fertilizers have a high content of nutrients required for plant growth. Consequently, they cause rapid and uncontrolled growth of vegetation and algae on the water surface when they end up in the water. This leads to clogging of water filters and contamination of drinking water. It also uses up all the oxygen leading to the destruction of marine life.

Also, aquatic microorganisms thrive on biodegradable substances, and when many of these chemicals are discharged into a waterway, the number of microorganisms increases. They use up all the oxygen in the water, and the depletion of oxygen leads to the death of aerobic microorganisms but promotes the growth of anaerobic organisms (eutrophication). In addition, certain anaerobic microorganisms contaminate the water by producing toxins such as sulfide derivatives and ammonia.

Some chemical contaminants do not dissolve in water, and, when suspended, they form a layer on the surface of the water, preventing oxygen penetration leading to oxygen depletion pollution. On the other hand, the particulate matter may settle at the bottom of the lake, ocean, or river, affecting the life on the floor of the river, lake, or ocean. In some cases, the material can comprise of harmful toxins.

In fact, the ability of a body of water to produce living material (the productivity of the water) results from a combination of chemical and physical factors. For example, water of low productivity generally is desirable for water supply or for swimming while relatively high productivity is required for the support of fish. Excessive productivity can result in choking by weeds and can cause odor problems. The growth of algae may become quite high in very productive waters, with the result that the concurrent decomposition of dead algae reduces oxygen levels in the water to low values (eutrophication).

When water pollution causes an algal bloom in a lake or marine environment, the proliferation of newly introduced nutrients stimulates plant and algae growth, which in turn reduces oxygen levels in the water. This scarcity of oxygen (eutrophication) suffocates plants and animals and can create dead zones in which the water is, to all intents and purposes, devoid of life. In certain cases, the harmful algal blooms can also produce neurotoxins that affect many forms of wildlife.

Moreover, the issue of eutrophication is due mainly to excessive, but inadvertent, introduction of domestic and industrial wastes, runoff from fertilized agricultural and urban areas, precipitation, and groundwater. The interaction of the natural processes within the lake with the artificial disturbance caused by human activities complicates the overall problem and leads to an accelerated rate of deterioration in lakes. Since a population increase necessitates an expanded utilization of lakes and streams, cultural eutrophication has become a major water resource problem throughout the world. Cultural eutrophication is reflected in changes in species composition, population sizes, and productivity in groups of organisms throughout the aquatic ecosystem.

Chemicals and heavy metals from industrial and municipal wastewater also contaminate waterways. These contaminants are toxic to aquatic life and often reduce the lifespan of an organism as well as the ability to reproduce, thereby accumulating in the food chain as predator eats prey. An example is the accumulation of mercury within various species of fish.

Life forms higher than algae and bacteria (e.g., fish) comprise a comparatively small fraction of the biomass in most aquatic systems. The influence of these higher life forms upon aquatic chemistry is minimal. However, aquatic life is strongly influenced by the physical and chemical properties of the body of water in which it lives.

Temperature, transparency, and turbulence are the three main physical properties affecting aquatic life. Low water temperatures result in slow biological processes, whereas high temperatures are fatal to most organisms. A difference of only a few degrees can produce large differences in the kinds of organisms present. Thermal discharges of hot water from power plants (cooling water) frequently kill temperature-sensitive fish while increasing the growth of fish and other species that are adapted to higher temperatures.

The transparency of water is particularly important in determining the growth of algae. Turbid water may not be very productive of biomass, even though it has the nutrients and optimum temperature. Turbulence is an important factor in mixing and transport processes in water. Some small organisms (plankton) depend upon water currents for their own mobility.

Water turbulence is largely responsible for the transport of nutrients to living organisms and of waste products away from them. It plays a role in the transport of oxygen, carbon dioxide, and other gases through a body of water and in the exchange of these gases at the water-atmosphere interface. Moderate turbulence is generally beneficial to aquatic life.

Biochemical oxygen demand, another important water-quality parameter, refers to the amount of oxygen utilized when the organic matter in a given volume of water is degraded biologically. A body of water with a high biochemical oxygen demand, and no means of rapidly replenishing the oxygen, obviously cannot sustain organisms that require oxygen. The degree of oxygen consumption by microbial oxidation of contaminants in water is called the biochemical oxygen demand (or biological oxygen demand).

The levels of nutrients in water frequently determine its productivity. Aquatic plant life requires an adequate supply of carbon (carbon dioxide, CO_2), nitrogen (nitrate, NO_3), phosphorus (orthophosphate, HPO_4^{2-}), and trace elements such as iron. In many cases, phosphorus is the limiting nutrient and is generally controlled in attempts to limit excess productivity. The salinity of water also determines the kinds of life forms present. Irrigation waters may pick up harmful levels of salt. Marine life obviously requires or tolerates salt water, whereas many freshwater organisms are intolerant of salt.

A majority of the important chemical reactions occurring in water, particularly those involving organic matter and oxidation-reduction processes, occur through bacterial intermediaries. Algae are the primary producers of biological organic matter (biomass) in water. Microorganisms are responsible for the formation of many sediment and mineral deposits; they also play the dominant role in secondary waste treatment.

Another example of waste control by oxidation involves oxidation of chemical waste materials in supercritical water. Supercritical water oxidation has been used to convert organic materials to carbon dioxide and is claimed to achieve destruction of 99.9%+ of chemicals such as polyols and amines that occur in liquid waste streams (Stadif, 1995).

See also: Aquasphere, Pollutant, Pollutant Adsorption, Pollutant – Persistent, Water.

Pollution

Pollution is the introduction of indigenous (beyond the natural abundance) and non-indigenous (artificial) gaseous, liquid, and solid contaminants into an ecosystem. The atmosphere and water and land systems have the ability to cleanse themselves of many pollutants within hours or days, especially when the effects of the pollutant are minimized by the natural constituents of the ecosystem. For example, the atmosphere might be considered to be self-cleaning as a result of rain. However, removal of some pollutants from the atmosphere (e.g., sulfates and nitrates) by rainfall results in the formation of acid rain that can cause serious environmental damage to ecosystems within the water and land systems. Pollutants, the elements of pollution, can be foreign substances or energies, or naturally occurring; when naturally occurring, they are considered contaminants when they exceed natural levels. Pollution is often classed as point source or nonpoint source pollution.

Sometimes, the term pollution is extended to include any substance when it occurs at such unnaturally high concentration within a system that it endangers the stability of that system. For example, water is innocuous and essential for life, and yet at high concentration, it could be considered a pollutant: if a person were to drink an excessive quantity of water, the physical system could be so overburdened that breakdown and even death could result. Another example is the potential of excessive noise to induce imbalance in the mental state of a person, resulting in malfunction and psychosis; this has been used as a weapon in warfare. The major forms of pollution by a refinery are: (i) air pollution, which is the release of chemicals and particulates into the atmosphere; common gaseous air pollutants include carbon monoxide and carbon dioxide, sulfur oxides, nitrogen oxides, particulate matter, and hydrocarbon derivatives, (ii) water pollution by the release of waste products and contaminants into surface runoff into river drainage systems, leaching into groundwater, liquid spills, wastewater discharges, eutrophication, and littering, and (iii) soil contamination occurs when chemicals are released by spill or underground leakage.

Pollution Control

Pollution control is a term used in environmental management refers to control of emissions and effluents into air, water, or soil. Without pollution control, the waste products from consumption, heating, agriculture, mining, manufacturing, transportation, and other human activities, whether they accumulate or disperse, will degrade the environment. In the hierarchy of controls, pollution prevention and waste minimization are more desirable than pollution control.

In order to evaluate the need and use of for pollution control systems, it is necessary to estimate the mean concentration of pollutants in ecologically sensitive zones and preventing their dangerous levels through a control of emission rates of the relevant sources of the pollutants. The direct estimates use the solutions of pollution transport model allow performing complete analysis of ecological situation. On the other hand, the adjoint estimates depend explicitly on the number, positions, and emission rates of the sources and the initial distribution of pollutants in the region.

Each control strategy develops quantitative criteria with the aim to avoid violations of existing environmental norms through reductions in the emission rates of sources. Such criteria are designed taking into account (i) the processes of dispersion and transformation of pollutants, (ii) the number of point sources to control, and (iii) the locations of the sources.

Polychlorobiphenyls

Polychlorobiphenyls (PCBs, polychlorobiphenyl derivatives) are a class of chemical compounds in which as few as two and as many as ten (the maximum) chlorine atoms are attached to the biphenyl molecule. Monochlorinated

biphenyls (i.e., one chlorine atom attached to the biphenyl molecule) are often included when describing PCBs. The general chemical structure of chlorinated biphenyls:

The benzene rings can rotate around the bond connecting them; the two extreme configurations are planar (the two benzene rings in the same plane) and the nonplanar in which the benzene rings are at a 90° angle to each other. The degree of planarity is largely determined by the number of substitutions in the ortho positions. The replacement of hydrogen atoms in the ortho positions with larger chlorine atoms forces the benzene rings to rotate out of the planar configuration. The benzene rings of non-ortho substituted polychlorobiphenyls, as well as mono-ortho substituted polychlorobiphenyls, may assume a planar configuration and are referred to as planar or coplanar congeners; the benzene rings of other congeners cannot assume a planar or coplanar configuration and are referred to as non-planar congeners.

The trade names of some commercial polychlorobiphenyl mixtures manufactured in other countries are Clophen (Germany), Fenclor (Italy), Kanechlor (Japan), and Phenoclor (France). The composition of commercial Clophen A-60 and Phenoclor DP-6 is similar to Aroclor 1260; that of Kanechlor 500 is similar to Aroclor 1254. Fenclor contains 100% decachlorobiphenyl.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs, also referred to as polynuclear aromatic hydrocarbons, PNAs) are a suite of compounds comprised of two or more condensed aromatic rings. They are found in many crude oil and alternate fuel mixtures, and they are predominantly introduced to the environment through natural and anthropogenic combustion processes.

Benzene (C_6H_6) is the simplest aromatic hydrocarbon and can have from one to six substituents attached to the central benzene core. An example of a benzene compound with just one substituent is toluene with a methyl group:

Polycyclic aromatic hydrocarbon derivatives are chemical compounds that consist of fused aromatic rings and do not contain heteroatoms or carry substituents (Table P-7). They occur in crude oil and are produced as by-products of fuel oil burning. As a pollutant, they are of concern because some compounds have been identified as carcinogenic, mutagenic, and teratogenic.

Table P-7 Examples of polycyclic aromatic hydrocarbons.

Chemical compound		Chemical compound	
Anthracene		Benzo(a)pyrene	
Chrysene		Coronene	
Corannulene		Naphthacene	
Naphthalene		Pentacene	
Phenanthrene		Pyrene	
Triphenylene		Ovalene	

See also: Peri-Condensed Aromatic Compounds, Polycyclic Compounds, Polynuclear Aromatic Compounds.

Polycyclic Compounds

In the field of organic chemistry, a polycyclic compound is an organic compound in which there are two or more closed rings of carbon atoms (Table P-8) and which can contain substructures of cycloalkanes (cycloparaffin hydrocarbons), aromatics, and other ring types that contain a heteroatoms such as nitrogen and/or oxygen and/or sulfur.

Table P-8 Examples of polycyclic aromatic compounds.

Chemical compound		Chemical compound	
Anthracene		Benzo[a]pyrene	
Chrysene		Coronene	
Corannulene		Naphthacene	
Naphthalene		Pentacene	
Phenanthrene		Pyrene	
Triphenylene		Ovalene	

The related term polycyclic organic matter (POM) defines a broad class of compounds that includes the polycyclic aromatic hydrocarbon compounds (PAHs, polynuclear aromatic compounds, PNAs), of which benzo[a]pyrene is a member.

Polycyclic organic matter is formed primarily from combustion and is present in the atmosphere in particulate form.

As a pollutant, polycyclic aromatic hydrocarbon derivatives are of concern because some compounds have been identified as carcinogenic, mutagenic, and teratogenic.

Polymer Waste

The disposal of the used polymeric materials is becoming a serious problem. Unlike natural polymers, most synthetic macromolecules cannot be assimilated by microorganisms. Although polymers represent slightly over 10% of total municipal waste, the problem of non-biodegradability is highlighted by overflowing landfills, polluted marine waters, and unsightly litter.

Total management of polymer wastes requires complementary combinations of biodegradation, incineration, and recycling. Biodegradation is the most desirable long-term future solution and requires intensive research and development before it becomes practical. On the other hand, incineration and recycling can become operational in a relatively short time for the improvement of the situation at present and in the near future.

Recycling of plastics that used to end up only at city landfills or incinerators is increasing and discarded plastic products and packaging make up a growing portion of Municipal Solid Waste (MSW).

Over the past two decades, recycling of plastics has dramatically increased. After years of predictions that plastics recycling would never be widespread because the processes were inefficient, too expensive, or not practical, the tide of waste headed to the landfill is slowly being turned.

A significantly important component of municipal solid waste is polymeric materials. Although polymer waste only accounts for 8.5% by mass of the total municipal solid waste disposed of in the United States, plastics represent over 28% v/v. Furthermore, most plastic wastes are not biodegradable and render a long-term waste management problem. The high volume-to-mass ratio and the inertness to biological reactions make the plastics and polymeric wastes the most important target for recycle, not for disposal. Polymeric wastes range from packaging materials used in the food industry to various parts in automobiles to high-density polyethylene (HDPE) containers for soft drinks and commercial liquids.

Within the next decades, the use of polymeric materials will continue to increase due to their versatility, functional values, and low energy requirements for production. The impetus to reuse the polymeric wastes instead of disposal in landfills is primarily due to the inability of polymers to rapidly degrade once dumped or buried at landfills.

There are a number of technologies available for the generation of fuel energy, either in gaseous or liquid form, from polymeric waste. These technologies include (i) pyrolysis, (ii) thermal cracking, (iii) catalytic cracking, and (iv) degradative extrusion as well as (v) partial oxidation. However, it is important to note that these are not the only processes available. As the technology advances, so do the processes used for the recovery of energy from wastes.

Pyrolysis of polymers is, by definition, the thermal decomposition of plastic waste back into oil or gas using heating processes under oxygen-starved or oxygen-deprived environment. This is the process typically used for waste-to-energy generation since it has several advantages. Besides being a proven technology, pyrolysis has a relatively good adaptability to fluctuations in the quality of the feedstock, simple to operate, and economical. In addition, refineries, which will utilize the chemically recycled polymers, already have pyrolysis units in operation.

Molten salts have also been successful at slightly lower operating temperatures. When the salts are used during a standard pyrolysis operation at 420°C (790°F), the gaseous fraction is minimized. This enables higher liquid and solid fractions to be recovered. While the nature of chemical reactions between the molten salts and polymeric waste is not yet completely understood, it does appear that production of a particular product mix is optimized by the presence of the salts. Typically, the recovered fractions consist of low-boiling oils, aromatic derivatives, paraffin waxes, and monomers. When pyrolysis utilizes molten salts, care must be taken to decrease the amount of corrosion and contamination to the pyrolysis chamber due to the salts.

Thermal cracking is similar to pyrolysis in that it is a high-temperature process. When polymeric wastes are cracked in an oxygen-free environment at temperatures above 480°C (900°F), a mixture of gas/liquid hydrocarbon is produced. At higher temperatures (650 to 760°C; 1,200 to 1,400°F), more of the gaseous product is generated. Conversely, at lower temperatures, up to 85% w/w of the product is a liquid hydrocarbon. Both the gas and liquid form of the converted mixed-polymeric waste can be utilized as a feed stream by crude oil facilities.

Catalytic cracking is similar to thermal cracking, but the primary difference is the addition of a catalyst to enhance the process. A typical catalytic cracker consists of two large reactor vessels: one vessel to react the feed over the hot catalyst and the other vessel to regenerate the spent catalyst by burning off carbon (fouled carbon on the catalytic surface) with air. Using two catalytic reactors enables the process to be run on a continuous basis.

Perhaps the most widely studied classification of catalysts for cracking operations is that of solid acid catalysts. The differences between the catalysts arise in the production of the coke and gas fractions. Formation of coke is not desirable since it causes catalytic deactivation by fouling and plugging the pore paths.

Regardless of the catalyst used, catalytic cracking, due to lower temperature operation, appears to be more technologically sound than pyrolysis. However, catalytic processes are often costlier than noncatalytic counterparts due to the costs involved in catalysts, catalytic reactors, and catalyst regeneration steps.

Pongamia Oil

Pongamia pinnata (Indian Beech Tree, Honge Tree, Pongam Tree, *Millettia Pinnata*) is a fast-growing evergreen tree which reaches 40 feet in height with up to a 55-foot spread, forming a broad, spreading canopy casting moderate shade. The six-to-nine-inch-long, pinnately compound, shiny dark green leaves are briefly deciduous, dropping for just a short period of time in early spring but being quickly replaced by new growth. Pongam is at its finest in the spring when the showy, hanging clusters of white, pink, or lavender, pea-like, fragrant blossoms appear, the clusters up to 10 inches long. The tree is believed to have originated in India and is native to a number of countries including India, Malaysia, Indonesia, Taiwan, Bangladesh, Sri Lanka, and Myanmar. It has also been naturalized in parts of eastern Africa, northern Australia, and Florida. Wherever it is grown, the wood (calorific value: 4,600 kcal/kg) is burned for cooking fuel. The thick oil from the seeds is used for illumination, as a kerosene substitute, and lubrication.

The seed oil (pongamia oil – other names for this oil include honge oil, kanuga oil, karanja oil, and pungai oil which has a high content of triglycerides) has been found to be useful in diesel generators, and, along with *Jatropha*, it is being explored in hundreds of projects throughout India and the third world as feedstock for biodiesel. It is especially attractive because it grows naturally through much of arid India, having very deep roots to reach water, and is one of the few crops well-suited to commercialization by countries that have large populations of rural poor. Several unelectrified villages have recently used pongamia oil, simple processing techniques, and diesel generators to create their own grid systems to run water pumps and electric lighting.

Porosity

The porosity (n) of a rock formation is the volume of voids in the formation divided to the total volume of the formations and is presented as a percentage. Thus:

$$\text{Porosity } (n) = (\text{volume of voids, } V_v) / (\text{total volume of the rock, } V_t)$$

The primary porosity is the inherent characteristic that is developed during the formation of the rock – examples are unconsolidated formations and sedimentary rocks have intergranular spaces. In basalts, the primary porosity is due to gas cavities, the lava tubes, and lava tunnels. The amount of pore space depends on the degree of compaction of the sediment (with compaction generally increasing with depth of burial), on the packing arrangement and shape of grains, on the amount of cementation, and on the degree of sorting. Typical cements are siliceous, calcareous or carbonate, or iron-bearing minerals. In consolidated rocks, the openings are primarily present as fractures, at joints, along bedding planes, and in the form of solution holes.

Secondary porosity is developed due to subsequent processes such as fracturing, jointing, and solution activities. In the igneous and metamorphic rocks as well as the hard sedimentary rocks, the porosity is secondary in nature.

The effective porosity, n_e , is the volume of pores that is available for transport of water, divided by the bulk volume. The effective porosity is slightly less than the porosity as part of the water that is molecularly bound to the pores or is stored in dead end pores does not participate in the flow. Porosity is a non-dimensional number, which could range from 0-1, it is often reported as a percentage (Table P-9). In the fractured rocks, the porosity depends upon the size of the individual fractures, joints, and other openings.

Table P-9 Porosity of different rock types.

Rock type	Range of porosity, %
Gravel	0.2-0.4
Sand	0.2-0.5
Silt	0.3-0.5
Clay	0.3-0.7
Fractured basalt	0.05-0.5
Karst limestone	0.05-0.5
Limestone, dolomite	0.0-0.2
Shale	0.0-0.2

Sedimentary rocks and soils generally have the highest porosities, mostly from primary, while secondary contributes to fracturing and dissolution. Igneous and metamorphic rocks generally have low primary porosity, with sometimes-significant secondary porosity (fractures, especially in volcanic rocks). Rounded grains have smaller pore spaces between them in relation to irregularly shaped grains. Compaction results in reduction in porosity due to weight of overburden.

Porphyryns

Porphyryns, which are complex derivatives of the basic material porphine, occur as part of the nitrogen-containing constituents of crude oil as well as bio-oil produced from certain types of biomass.

The porphyryns series is based on the pyrrole system. The porphyryns are actually based on a conjugated cyclic structure (porphine), which consists of four pyrrole rings linked together in the 2 and 5 positions by methine (=CH-) bridges:

Although porphine itself does not appear to exist in nature, structures based on this system are important to the existence of plant and animal life. In the animal kingdom, the porphine system occurs as hemoglobin (in the heme part of the molecule) in the red corpuscles of the blood and acts as an oxygen carrier to the lungs and to the body tissue. In the plant kingdom, porphyrin occurs in the chlorophyll found as the green coloring of leaves and stems which is essential for photosynthesis.

The porphyrin compounds are recognized as the degradation products of the chlorophyll (photosynthetic pigments of plants and some bacteria) and of the hemes and hematins, the respiratory pigments of both plants and animals. Most, if not all, of the porphyrin material in crude oils is completed with a metal, of which vanadium is the most important, followed by nickel, iron, as well as copper may also be present.

Porphyrins are a naturally occurring chemical species that exist in crude oil and usually occur in the non-basic portion of the nitrogen-containing concentrate. They are not usually considered among the usual nitrogen-containing constituents of crude oil, nor are they considered a metallo-containing organic material that also occurs in some crude oils. As a result of these early investigations, there arose the concept of porphyrins as biomarkers that could establish a link between compounds found in the geosphere and their corresponding biological precursors.

Porphyrins are derivatives of porphine [that consists of four pyrrole molecules joined by methine ($-\text{CH}=\text{}$) bridges]. The methine bridges establish conjugated linkages between the component pyrrole nuclei, forming a more extended resonance system. Although the resulting structure retains much of the inherent character of the pyrrole components, the larger conjugated system gives increased aromatic character to the porphine molecule. Furthermore, the imine functions ($-\text{NH}-$) in the porphine system allow metals such as nickel to be included into the molecule through chelation.

A large number of different porphyrin compounds exist in nature or have been synthesized. Most of these compounds have substituents other than hydrogen on many of the ring carbons. The nature of the substituents on porphyrin rings determines the classification of a specific porphyrin compound into one of various types according to one common system of nomenclature. Porphyrins also have well-known trivial names or acronyms that are often in more common usage than the formal system of nomenclature.

When one or two double bonds of a porphyrin are hydrogenated, a chlorin or a phlorin is the result. Chlorins are components of chlorophylls and possess an iso-cyclic ring formed by two methylene groups bridging a pyrrole-ring carbon to a methine carbon. Geological porphyrins that contain this structural feature are assumed to be derived from chlorophylls. Etioporphyrin derivatives are also commonly found in geological materials and have no substituents (other than hydrogen) on the methine carbons. Benzoporphyrins and tetrahydrobenzo-porphyrin derivatives also have been identified in geological materials. These compounds have either a benzene ring or a hydrogenated benzene ring fused onto a pyrrole unit.

Positron

The positron (sometimes referred to as the antielectron, the antiparticle, or the antimatter counterpart of the electron) has an electric charge of $+1 e$, a spin of $1/2$ (the same as the electron), and has the same mass as an electron. When a positron collides with an electron, destruction occurs, and if this collision occurs at a low energy level, it results in the production of two or more photons. A positron can be created by positron emission radioactive decay (through weak interactions), or by pair production from a sufficiently energetic photon which is interacting with an atom in a material.

More specifically, positrons are produced naturally in the β^+ decay of naturally occurring radioactive isotopes and by the interaction of gamma quanta (emitted by radioactive nuclei) with matter. In the radioactive decay process, unstable atomic nuclei due to too many protons relative to the number of neutrons and the nucleus decays to stable form by converting a proton to a neutron after which a positron is ejected to conserve electric charge. The positron annihilates with an electron, releasing two anti-colinear high-energy photons.

Antineutrinos are another kind of antiparticle produced by natural radioactivity (β^- decay). Positrons are also produced in gamma-ray flashes created by electrons accelerated by strong electric fields in the clouds. Antiparticles, of which the most common are positrons due to their low mass, are also produced in any environment with a sufficiently high temperature (mean particle energy greater than the pair production threshold).

Positron production from radioactive can be considered both artificial and natural production, as the generation of the radioisotope can be natural or artificial. Perhaps the best known naturally-occurring radioisotope which produces positrons is potassium-40 (^{40}K) potassium-40, a long-lived isotope of potassium which occurs as a primordial isotope of potassium.

See also: Electron, Radioactive Decay.

Possible Reserves

While probable reserves are those reserves of crude oil that are nearly certain but approximately which a slight doubt exists, possible reserves are those reserves of crude oil with an even greater degree of uncertainty related to recovery but about which there is some information. An additional term potential reserves is also used on occasion; these reserves are based upon geological information related to the types of sediments where such resources are likely to occur and they are considered to represent an educated guess (Table P-10).

Table P-10 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

There are the so-called undiscovered reserves, which are a little more than figments of imagination! The terms undiscovered reserves or undiscovered resources should be used with caution, especially when applied as a means of estimating reserves of crude oil reserves. The data are very speculative and are regarded by many energy scientists as having little value other than unbridled optimism.

Post-Combustion Cleaning

Post-combustion cleaning involves removal of sulfur dioxide (SO_2), nitrogen oxides (NO_x), and/or particulates from the flue gas after it exits the boiler. Conventional technology (wet scrubbers) uses limestone or lime (and in some cases other alkaline agents) to remove sulfur pollutants from the flue gas before it exits the stack. Such processes can be plagued by corrosion and plugging and also produce a wet waste product (sludge) which has high disposal costs.

Advanced post-combustion cleaning technologies encompass two approaches which are (i) using the existing flue gas ductwork to inject a sorbent and (ii) inserting one or more separate vessels into the downstream ductwork where pollutant absorbents are added. These advanced technologies offer several advantages over conventional technologies such as (i) regeneration of the sulfur-absorbing chemical, (ii) increased residence time with the sulfur absorbent, (iii) reduced physical size requirements, and (iv) a dry, environmentally benign, waste product that may have commercial value.

In-duct sorbent cleaning occurs out, as the name indicates, inside the ductwork leading from the boiler to the smokestack. Sulfur dioxide absorbers (e.g., hydrated lime) are sprayed into the center of the duct. By controlling the humidity of the flue gas and the spray pattern of the sorbent, 50 to 70% of the sulfur dioxide can be removed and the reaction produces dry particles that can be collected downstream. In-duct sorbent injection is an attractive option for retrofitting smaller, older plants where space requirements might be limited.

When separate vessels are used, one or more process chambers are inserted in the flue gas ductwork, and various sorbents are injected to remove the pollutants. The separate vessels provide a longer residence time for the absorbent

to react with the gas, and pollutant capture is greater. This approach has the potential of capturing more than 90% of the pollutants. Technologies such as the spray dryer and selective catalytic reduction represent approaches that use separate vessels.

See also: Gas Cleaning Gas Processing, Gas Treating.

Potatoes

Potatoes are somewhat lower in total carbohydrates than sweet potatoes; thus, alcohol yields would be less even if total yields were similar.

Potatoes are potentially a lucrative source of biofuel. Corn has been the biofuel crop of choice, for two reasons which are (i) corn is energy-rich and (ii) corn is abundant. However, as biofuel gained in popularity, it created a problem: a lack of corn to actually eat.

Potatoes have all the handling advantages of sweet potatoes and are easier to establish, since seed pieces rather than transplants are used. The technology for making alcohol from potatoes is well developed, and this crop is worthy of consideration in areas where high yields are possible.

Sweet potatoes have been shown to yield two to three times as much carbohydrate for fuel ethanol production as field corn grown in the same areas. In fact, the sweet potato carbohydrate yields approached the lower limits of those produced by sugarcane, the highest-yielding ethanol crop. Sweet potatoes may also be a viable renewable fuel alternative as biofuel source.

See also: Biomass.

Potential Reserves

The term potential reserves is used on occasion to indicate reserves that are based upon geological information related to the types of sediments where such resources are likely to occur and they are considered to represent an educated guess (Table P-11).

Table P-11 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

The term inferred reserves is also commonly used in addition to, or in place of, potential reserves. Inferred reserves are regarded as of a higher degree of accuracy than potential reserves, and the term is applied to those reserves that are estimated using an improved understanding of reservoir frameworks. The term also usually includes those reserves that can be recovered by further development of recovery technologies.

Potential reserves are also those reserves where the relationship between the market price for the resource and the amount of the resource that can be profitably extracted at that price. The higher the price, the greater the potential reserves.

Potential reserves are also those reserves where the relationship between the market price for the resource and the amount of the resource that can be profitably extracted at that price. The higher the price, the greater the potential reserves.

See also: Reserves.

Pour Point

The pour point of a liquid fuel is the lowest temperature at which the fuel will pour or flow under prescribed conditions. When compared to reservoir temperature, it is an indication of whether or not the oil is pumpable without the input of additional heat energy. Also, the pour point is the minimum temperature of a liquid, particularly a lubricant, after which, on decreasing the temperature, the liquid ceases to flow.

It is also useful to note that failure of oil to flow at the pour point may also be due to the effect of viscosity or the previous thermal history of the specimen. Therefore, the pour point may give a misleading view of the handling properties of the oil. Additional fluidity or pumpability tests may also be undertaken. An approximate range of pour point can be observed from the upper and lower pour point of the sample.

The pour point test was originally applied to crude oil to crude oil products that had a high wax content. More recently, the pour point, like the viscosity, is determined principally for use in pumping and pipeline design calculations. Difficulty occurs in these determinations with waxy fuels that begin to exhibit irregular flow behavior when wax begins to separate. These fuels possess viscosity relationships that are difficult to predict in pipeline operation. In addition, some waxy fuels are sensitive to heat treatment that can also affect their viscosity characteristics. This complex behavior limits the value of viscosity and pour point tests on waxy crude oils. At the present time, long crude oil pipelines and the increasing production of waxy crude oils make an assessment of the pumpability of a wax-containing crude oil through a given system a matter of some difficulty that can often only be resolved after field trials.

To measure the pour point, the sample is cooled inside a cooling bath to allow the formation of wax crystals. At approximately 9°C (16°F) above the expected pour point, and for every subsequent 3°C (5°F), the test jar is removed and tilted to check for surface movement. When the specimen does not flow when tilted, the jar is held horizontally for 5 seconds. If it does not flow, 3°C (5°F) is added to the corresponding temperature and the result is the pour point temperature.

Precipitation

Precipitation follows one of two processes which are (i) collision-coalescence which occurs when water droplets collide and combine together to form larger droplets as larger droplets are pulled earthward by gravity and updrafts can recycle the droplets through the cloud, increasing droplet size, and (ii) Bergeron processes occur where temperatures fall below freezing and pure water droplets remain liquid until supercooled to temperatures of more than -20°C (-4°F) at which time miniature ice crystals or supercooled water droplets may act as condensation surfaces. However, the density of water vapor in the air prior to saturation is slightly less adjacent to ice surfaces than water surfaces. Consequently, water vapor is added to the growing ice crystals (by deposition) rather than the water droplets. Eventually, precipitation of ice or snow occurs unless the frozen water is warmed as it falls through the atmosphere, resulting in rain.

See also: Acid Rain, Chemical Precipitation, Supercritical Fluid Precipitation.

Pressure Swing Adsorption

Pressure swing adsorption is generally the purification method of choice for steam reforming units because of its production of high purity hydrogen and is also used for purification of refinery off-gases, where it competes with membrane systems.

Pressure-swing adsorption units use beds of solid adsorbent to separate impurities from hydrogen streams leading to high-purity high-pressure hydrogen and a low-pressure tail gas stream containing the impurities and some of the hydrogen. The beds are then regenerated by depressurizing and purging. Part of the hydrogen (up to 20% v/v) may be lost in the tail gas.

Pressure swing adsorption is generally the purification method of choice for steam reforming units because of its production of high purity hydrogen and is also used for purification of refinery off-gases, where it competes with membrane systems.

Many hydrogen plants that formerly used a wet scrubbing process for hydrogen purification are now using the *pressure-swing adsorption* (PSA) concept for purification. The pressure swing adsorption process is a cyclic process that uses beds of solid adsorbent to remove impurities from the gas and generally produces higher purity hydrogen (99.9 volume percent purity compared to less than 97 volume per cent purity). The purified hydrogen passes through the adsorbent beds with only a tiny fraction absorbed, and the beds are regenerated by depressurization followed by purging at low pressure.

When the beds are depressurized, a waste gas (or *tail gas*) stream is produced and consists of the impurities from the feed (carbon monoxide, carbon dioxide, methane, and nitrogen) plus some hydrogen. This stream is burned in the reformer as fuel and reformer operating conditions in a pressure swing adsorption plant are set so that the tail gas provides no more than approximately 85% of the reformer fuel. This gives good burner control because the tail gas is more difficult to burn than regular fuel gas and the high content of carbon monoxide can interfere with the stability of the flame. As the reformer operating temperature is increased, the reforming equilibrium shifts, resulting in more hydrogen and less methane in the reformer outlet and hence less methane in the tail gas.

Pressurized Water Reactor

The pressurized water reactor (PWR) is a common nuclear power reactor design in which very pure water is heated to a high temperature by fission, kept under high pressure to prevent it from boiling, and converted to steam by a steam generator rather than by boiling, as in a boiling water reactor. The resulting steam is used to drive turbines, which activate the generators to produce electrical power.

More specifically by stages, in a typical commercial pressurized water reactor, the following process occurs: (i) the core inside the reactor vessel creates heat, (ii) pressurized water in the primary coolant loop carries the heat to the steam generator, (iii) inside the steam generator, heat from the primary coolant loop vaporizes the water in a secondary loop, producing steam, and (iv) the steam line directs the steam to the main turbine, causing it to turn the turbine generator, which produces electricity.

The unused steam is exhausted to the condenser, where it is condensed into water which is pumped out of the condenser with a series of pumps, reheated, and pumped back to the steam generator. The core of the reactor contains fuel assemblies that are cooled by water circulated using electrically powered pumps. These pumps and other operating systems in the plant receive their power from the electrical grid. If offsite power is lost, emergency cooling water is supplied by other pumps, which can be powered by onsite diesel generators. Other safety systems, such as the containment cooling system, also need electric power. A pressurized water reactor may contain between 150 and 200 fuel assemblies.

Pressurized water reactors have advantages over the other light water reactors and earlier generation nuclear sites. One major advantage of this reactor is that it is easy to operate because less power is being produced as the heat increases. In addition, the core of the reactor contains less fissile material, decreasing the chances of additional fission events to occur, making the reactor safer and more controllable. In other words, then reactor contains less

fissile material than is required for the reactor to go prompt critical. Also, the most advantageous element of the pressurized water reactor is the turbine cycle. Since the primary and secondary loops are separate, water can never be contaminated by radioactive material in the main system loop. Conclusively, the water from the primary and secondary loops will never touch or mix, so there is no chance for contamination.

See: Nuclear Reactor – Pressurized Water Reactor.

Primary Biomass Feedstock

Primary biomass is biomass that is harvested or collected from the field or forest where it is grown and includes all terrestrial plants now used for food, feed, fiber, and fuel wood. All plants in natural and conservation areas (as well as algae and other aquatic plants growing in ponds, lakes, oceans, or artificial ponds and bioreactors) are also considered primary biomass.

Examples of primary biomass feedstocks currently being used for bioenergy include grains and oilseed crops used for transportation fuel production, plus some crop residues (such as orchard trimmings and nut hulls) and some residues from logging and forest operations that are currently used for heat and power production. In the future, it is anticipated that a larger proportion of the residues inherently generated from food crop harvesting, as well as a larger proportion of the residues generated from ongoing logging and forest operations, will be used for bioenergy. Additionally, as the bioenergy industry develops, both woody and herbaceous perennial crops will be planted and harvested specifically for bioenergy and product end-uses.

Primary biomass is produced directly by photosynthesis and includes all terrestrial plants now used for food, feed, fiber, and fuelwood. All plants in natural and conservation areas (as well as algae and other aquatic plants growing in ponds, lakes, oceans, or artificial ponds and bioreactors) are also considered primary biomass. However, only a small portion of the primary biomass produced will ever be harvested as feedstock material for the production of bioenergy and bioproducts.

Primary biomass feedstocks are thus primary biomass that is harvested or collected from the field or forest where it is grown. Examples of primary biomass feedstocks currently being used for bioenergy include grains and oilseed crops used for transportation fuel production, plus some crop residues (such as orchard trimmings and nut hulls) and some residues from logging and forest operations that are currently used for heat and power production. In the future, it is anticipated that a larger proportion of the residues inherently generated from food crop harvesting, as well as a larger proportion of the residues generated from ongoing logging and forest operations, will be used for bioenergy. Additionally, as the bioenergy industry develops, both woody and herbaceous perennial crops will be planted and harvested specifically for bioenergy and bioproducts' end-uses.

Primary Gasification

Gasification is the thermal conversion of organic matter by partial oxidation into a gaseous product called synthesis gas which consists predominantly of hydrogen (H_2), carbon monoxide (CO), and small amounts of methane (CH_4), water vapor (H_2O), carbon dioxide (CO_2), nitrogen (N_2), and tar. The oxidant used for the gasification process can be air (hence, the occurrence of nitrogen in the gaseous product), pure oxygen, steam, or a mixture of these gases.

Air-based gasifiers typically produce a product gas containing a relatively high concentration of nitrogen with a low heating value. Oxygen and steam-based gasifiers produce a product gas containing a relatively high concentration of hydrogen and carbon monoxide, with a higher heating value. A significant amount of char is always produced in gasification which needs to be further processed and/or burned.

On the other hand, primary gasification is the initial step in the gasification process and involves thermal decomposition of the raw feedstock via various chemical processes and many schemes involve pressures ranging from atmospheric to 1,000 psi. Air or oxygen may be admitted to support combustion to provide the necessary heat. The product is usually a low heat-content (low-Btu) gas ranging from a carbon monoxide/hydrogen mixture to

mixtures containing varying amounts of carbon monoxide, carbon dioxide, hydrogen, water, methane, hydrogen sulfide, nitrogen, and typical products of thermal decomposition such as tar (themselves being complex mixtures, hydrocarbon oils, and phenols).

A solid char product may also be produced, and may represent the bulk of the weight of the original feedstock. This type of coal being processed determines (to a large extent) the amount of char produced and the analysis of the gas product.

See also Gasification, Secondary Gasification.

Primary Wood-Using Mill

A primary wood-using mill is a mill that converts round wood products into other wood products; common examples are sawmills that convert saw logs into lumber and pulp mills that convert pulpwood round wood into wood pulp.

Probable Reserves

Probable reserves are those reserves of crude oil that are nearly certain but about which a slight doubt exists (Table P-12).

Table P-12 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Possible reserves are those reserves of crude oil with an even greater degree of uncertainty relayed to recovery but about which there is some information. An additional term potential reserves is also used on occasion; these reserves are based upon geological information related to the types of sediments where such resources are likely to occur, and they are considered to represent an educated guess. Then, there are the so-called undiscovered reserves, which are little more than figments of the imagination! The terms undiscovered reserves or undiscovered resources should be used with caution, especially when applied as a means of estimating reserves of crude oil reserves. The data are very speculative and are regarded by many energy scientists as having little value other than an optimistic approach to reserve estimation.

Process Gas

The term process gas is often applied to gas produced in a refinery but can also be applied to a gas stream produced form alternate energy sources. The gas varies in composition and volume, depending on the origin of the process feedstock and process parameters. In fact, the terms refinery gas and petroleum gas are often used to identify liquefied petroleum gas or even gas that emanates as light ends (which are composed of gases and volatile liquids) from the atmospheric distillation unit or from any one of several other refinery processes. In the current context, the term process gas also includes the gaseous effluents from a biorefinery or from any biomass processing plant insofar as

similar constituents to those in refinery gas will also occur (but not to the same extent) from the thermal treatment of biomass.

In the refinery, process gas is produced in considerable quantities during the different refining processes and is used as fuel for the refinery itself and as an important feedstock for the production of petrochemicals. It consists mainly of hydrogen (H_2), methane (CH_4), ethane (C_2H_6), propane (C_3H_8), butane (C_4H_{10}), and olefins ($RCH=CHR^1$, where R and R^1 can be hydrogen or a methyl group) and may also include off-gases from petrochemical processes. Olefins such as ethylene ($CH_2=CH_2$, boiling point: $-104^\circ C$, $-155^\circ F$), propene (propylene, $CH_3CH=CH_2$, boiling point: $-47^\circ C$, $-53^\circ F$), butene (butene-1, $CH_3CH_2CH=CH_2$, boiling point: $-5^\circ C$, $23^\circ F$) *iso*-butylene ($(CH_3)_2C=CH_2$, $-6^\circ C$, $21^\circ F$), *cis*- and *trans*-butene-2 ($CH_3CH=CHCH_3$, boiling point: ca. $1^\circ C$, $30^\circ F$), and butadiene ($CH_2=CHCH=CH_2$, boiling point: $-4^\circ C$, $24^\circ F$) as well as higher boiling olefins are produced by various refining processes.

Also in the refinery, still gas is broad terminology for low-boiling hydrocarbon mixtures and is the lowest boiling fraction isolated from a distillation (*still*) unit in the refinery. If the distillation unit is separating light hydrocarbon fractions, the still gas will be almost entirely methane with only traces of ethane (CH_3CH_3) and ethylene ($CH_2=CH_2$). If the distillation unit is handling higher-boiling fractions, the still gas might also contain propane ($CH_3CH_2CH_3$), butane ($CH_3CH_2CH_2CH_3$), and their respective isomers. Fuel gas and still gas are terms that are often used interchangeably, but the term fuel gas is intended to denote the product's destination-to be used as a fuel for boilers, furnaces, or heaters.

A group of refining operations that contributes to gas production are the thermal cracking and catalytic cracking processes. The thermal cracking processes (such as the coking processes) produce a variety of gases, some of which may contain olefin derivatives ($>C=C<$). In the visbreaking process, fuel oil is passed through externally fired tubes and undergoes liquid phase cracking reactions, which result in the formation of lower-boiling fuel oil components. Substantial quantities of both gas and carbon are also formed in coking (both fluid coking and delayed coking) in addition to the middle distillate and naphtha. When coking a residual fuel oil or heavy gas oil, the feedstock is preheated and contacted with hot carbon (coke) which causes extensive cracking of the feedstock constituents of higher molecular weight to produce lower-molecular-weight products ranging from methane, via liquefied petroleum gas(es) and naphtha, to gas oil and heating oil. Products from coking processes tend to be unsaturated, and olefin-type components predominate in the tail gases from coking processes.

The various catalytic cracking processes, in which higher-boiling gas oil fractions are converted into gaseous products, various naphtha fractions, fuel oil, and coke by contacting the feedstock with the hot catalyst. Thus, both catalytic and thermal cracking processes, the latter being now largely used to produce chemical raw materials, result in the formation of unsaturated hydrocarbon derivatives, particularly ethylene ($CH_2=CH_2$), but also propylene (propene, $CH_3CH=CH_2$), isobutylene [isobutene, $(CH_3)_2C=CH_2$], and the *n*-butenes ($CH_3CH_2CH=CH_2$, and $CH_3CH=CHCH_3$) in addition to hydrogen (H_2), methane (CH_4) and smaller quantities of ethane (CH_3CH_3), propane ($CH_3CH_2CH_3$), and butane isomers [$CH_3CH_2CH_2CH_3$, $(CH_3)_3CH$]. Diolefins such as butadiene ($CH_2=CHCH=CH_2$) and are also present.

In a series of reforming processes, distillation fractions (as well as similar fractions from bio-oil processing) which include paraffin derivatives, and naphthene derivatives (cyclic non-aromatic) are treated in the presence of hydrogen and a catalyst to produce lower-molecular-weight products or are isomerized to more highly branched hydrocarbon derivatives. Also, the catalytic reforming process not only results in the formation of a liquid product of higher octane number but also produce substantial quantities of gaseous products.

The composition of these gases varies in accordance with process severity and the properties of the feedstock. The gaseous products are not only rich in hydrogen but also contain hydrocarbon derivatives from methane to butane derivatives, with a preponderance of propane ($CH_3CH_2CH_3$), *n*-butane ($CH_3CH_2CH_2CH_3$), and isobutane [$(CH_3)_3CH$]. Since all catalytic reforming processes require substantial recycling of a hydrogen stream, it is normal to separate reformer gas into a propane ($CH_3CH_2CH_3$) and/or a butane [$CH_3CH_2CH_2CH_3/(CH_3)_3CH$] stream, which becomes part of the refinery liquefied petroleum gas production, and a lower-boiling gaseous fraction, part of which is recycled.

A further source of refinery gas is produced by the hydrocracking process which is a high-pressure pyrolysis process carried out in the presence of fresh and recycled hydrogen. The feedstock is again heavy gas oil or residual fuel

oil, and the process is mainly directed at the production of additional middle distillates and gasoline. Since hydrogen is to be recycled, the gases produced in this process again must be separated into lighter and heavier streams; any surplus recycle gas and the liquefied petroleum gas from the hydrocracking process are both saturated.

Both hydrocracker and catalytic reformer tail gases are commonly used in catalytic desulfurization processes. In the latter, feedstocks ranging from light to vacuum gas oils are passed at pressures on the order of 500 to 1,000 psi with hydrogen over a hydrofining catalyst. This results mainly in the conversion of organic sulfur compounds to hydrogen sulfide:

The process also has the potential to produce lower-boiling hydrocarbon derivatives by hydrocracking. Refinery gas, usually in more than one stream, is typically treated for hydrogen sulfide removal, and gas sales are usually on a thermal content (calorific value, heating value) basis with some adjustment for variation in the calorific value and hydrocarbon type.

See also: Refining.

Process Selection – Gas Treating

Each of the gas treating processes has advantages relative to the others for certain applications; therefore, in selection of the appropriate process, the following facts should be considered: (i) tail gas clean-up requirements, (ii) type and concentration of impurities in the sour gas, (iii) specifications for the residue gas, (iv) specifications for the acid gas, (v) temperature and pressure at which the sour gas is available and at which the sweet gas must be delivered, (vi) volume of gas to be processed, (vii) hydrocarbon composition of the gas, and (viii) selectivity required for acid gas removal.

Decisions in selecting a gas treating process can many times be simplified by gas composition and operating conditions. High partial pressures (50 psi) of acid gases enhance the probability of using a physical solvent. The presence of significant quantities of high-boiling hydrocarbon derivatives in the feed discourages using physical solvents. Low partial pressures of acid gases and low outlet specifications generally require the use of amines for adequate treating.

In general, the batch and amine processes are used for over 90% of all onshore wellhead applications. Amine processes are preferred when the lower operating cost, the chemical cost for this process, is prohibitive, and justifies the higher equipment cost. The key is the sulfur content of the feed gas where below 20 pounds of sulfur per day, batch processes are more economical, and over 100-pound sulfur per day amine solutions are preferred.

See also: Gas Cleaning.

Process Selectivity

Process selectivity indicates the preference with which the process removes one acid gas component relative to (or in preference to) another. For example, some processes remove both hydrogen sulfide and carbon dioxide while other processes are designed to remove hydrogen sulfide only. It is important to consider the process selectivity for, say, hydrogen sulfide removal compared to carbon dioxide removal that ensures minimal concentrations of these components in the product, thus the need for consideration of the carbon dioxide to hydrogen sulfide in the gas stream.

See also: Gas Cleaning, Gas Processing.

Process Wastes

In any chemical production operation, the unit process operations that produce a variety of products from various feedstocks and feedstock blend and some of the wastes are present in air emissions, wastewater, or solid wastes.

Emissions are also created through the combustion of fuels, and as by-products of chemical reactions occurring when crude oil fractions are upgraded. A large source of air emissions is, generally, the process heaters and boilers that produce carbon monoxide, sulfur oxides, and nitrogen oxides, leading to pollution and the formation of acid rain.

Hence, there is the need for gas-cleaning operations on a production site so that such gases are cleaned from the gas stream prior to entry into the atmosphere.

In addition, some processes create considerable amounts of particulate matter and other emissions from catalyst regeneration or decoking processes. Volatile chemicals and hydrocarbon derivatives are also released from equipment leaks, storage tanks, and wastewaters. Other cleaning units such as the installation of filters, electrostatic precipitators, and cyclones can mitigate part of the problem.

Process wastewater is also a significant effluent from a number of refinery processes. Atmospheric distillation and vacuum distillation create the largest volumes of process wastewater, approximately 26 gallons per barrel of oil processed. Fluid catalytic cracking and catalytic reforming also generate considerable amounts of wastewater (15 and 6 gallons per barrel of feedstock, respectively). A large portion of wastewater from these three processes is contaminated with oil and other impurities and must be subjected to primary, secondary, and sometimes tertiary water treatment processes, some of which also create hazardous waste.

Wastes and by-products are produced by a number of processes. Residuals produced during refining can be but are not necessarily wastes. They can be recycled or regenerated, and in many cases do not become part of the waste stream but are useful products. For example, processes utilizing caustics for neutralization of acidic gases or solvent (e.g., alkylation, sweetening/chemical treating, and lubricating oil manufacture) create the largest source of residuals in the form of spent caustic solutions. However, nearly all of these caustics are recycled.

The treatment of wastewater from various processes generates the next largest source of residuals in the form of biomass sludge from biological treatment and pond sediments. Water treatment of oily wastewater also produces a number of sludge materials associated with oil-water separation processes. Such sludge is often recycled in the refining process and is not considered waste.

Producer Gas

Producer gas is mainly carbon monoxide with smaller amounts of hydrogen, methane, and variable amounts of nitrogen (Table P-13), obtained from partial combustion of coal or coke in air or oxygen, having a heat content of 110 to 160 Btu/ft³ (air combustion) or 400 to 500 Btu/ft³ (oxygen combustion).

Table P-13 Typical composition of producer gas.

Source	Coal/coke	Wood
	-----Gas constituent-----	
	%, v/v	%, v/v
Hydrogen	20-22	12-15
Carbon monoxide	19-20	20-22
Carbon dioxide	12-14	9-11
Methane	2-5	2-3
Nitrogen	50-60	50-54

The gas is produced by blowing air and sometimes steam through an incandescent fuel bed (the process is self-heating). The reaction with air is exothermic, but insufficient air is added; hence, carbon monoxide is produced. Steam addition results in the formation of hydrogen by the water gas reaction. This is endothermic and hence balances out the exothermic air reaction. Producer gas is low calorific value and is hence typically used as an on-site fuel gas.

In the process – using coal as the example, of the carbonaceous feedstock – air is blown through an incandescent bed of coal. The amount of air is sufficient to maintain the process temperature but insufficient to complete the combustion reaction. The gas products is a mixture containing approximately 50% v/v nitrogen, from the air, 29% v/v carbon monoxide, due to incomplete combustion of the feedstock, and 4% v/v carbon dioxide, as well as sundry other products, including hydrocarbon derivatives. The heat content of the gas is low and, although not suitable for distribution to consumers, can be used on site as a fuel gas. In order to modify the product distribution, steam can be used in the process, and endothermic reactions (such as the water gas reaction) result in the formation of hydrogen.

Initially, the oxidation of the feedstock (coal) in the presence of the available oxygen occurs after which there is competition for oxygen between the carbon and the water gas reactions occur:

The ratio of steam and air may be used to modify the composition of the gas that is produced.

See also: Gasification.

Product Analysis

The chemical composition of products from alternate energy sources is, like the analysis of products from crude oil and other fossil fuel sources, complex but is a necessary part of product identification and quality. These two criteria make it essential that the most appropriate analytical methods are selected from a comprehensive list of methods and techniques that are used for the analysis of samples.

The analysis of a biomass-related feedstock for the percentages of carbon, hydrogen, nitrogen, oxygen, and sulfur is perhaps the first method used to examine the general nature, and perform an evaluation, of a feedstock. The atomic ratios of the various elements to carbon (i.e., H/C, N/C, O/C, and S/C) are frequently used for indications of the overall character of the feedstock. It is also of value to determine the amounts of trace elements, such as

vanadium, nickel and other metals, in a feedstock since these materials can have serious deleterious effects on catalyst performance during refining by catalytic processes.

Using bio-oil as the example, valuable information can be obtained from the true boiling point (TBP) curve which is a function of percent weight distilled and temperature, that is, a boiling point distribution. However, the boiling range does not convey much detail about chemical reactivity of the product. In addition to the boiling point distribution, it is possible to measure bulk physical properties, such as specific gravity and viscosity that have assisted in the establishment of certain empirical relationships for further processing from the *true boiling point* curve. Many of these relationships include assumptions that are based on experience with a range of feedstocks. However, the chemical aspects of refining feedstocks that contain different proportions of chemical species emphasize the need for more definitive data that would enable more realistic predictions to be made of feedstock behavior in upgrading operations. Any of the methods described herein might also be applied to the analysis of sample for environmental purposes.

The importance of chemical and physical properties is dependent upon the purity of the product. In the strictest sense, most gaseous, liquid, and solid products are complex chemical mixtures and typically contain hydrocarbon derivatives and non-hydrocarbon derivatives that confer properties on the mixture that may not be reflected in the composition. Therefore, it is necessary to apply various test methods to feedstocks and products to determine if the material is suitable for processing and (in the case of the products) for sale with a designated use in mind. The more common tests are introduced in the following sub-sections – these tests are presented in alphabetical order with no preference given to any particular test method.

Finally, an important aspect of feedstock analysis is the feedstock assay which is necessary because of the wide range of composition of, in the current context, the various biomass-related feedstocks.

An efficient and meaningful assay is derived from a series of test data that give an accurate description of feedstock quality and allow an indication of feedstock behavior during the conversion to products. The analyses are performed to determine whether each batch of a feedstock is suitable for conversion and upgrading purposes. The information required is feedstock dependent and to obtain the necessary information, two different analytical schemes are commonly used and these are: (i) a comprehensive assay and (ii) an inspection assay.

A comprehensive (or full) assay is more complex (as well as time-consuming and costly) than the inspection assay and is usually only performed only when a new batch (and previous untested) feedstock comes on stream, or when the inspection assay indicates that significant changes in the composition of the feedstock oil have occurred. Except for these circumstances, a comprehensive assay of a particular feedstock may involve at least the determination of (i) the elemental composition in terms of the carbon content, the hydrogen content, the nitrogen content, the oxygen content, the sulfur content, and the metals content as well as the types of metals. Other test methods (presented alphabetically but which are feedstock dependent and process dependent) that can be included in the comprehensive assay include (i) boiling point distribution, (ii) density, specific gravity, and API gravity, (iii) emulsion formation, (iv) evaporation, (v) fire point and flash point, (vi) fractionation, (vii) molecular weight, (viii) pour point, (ix) sulfur content, (x) surface tension and interfacial tension, (xi) total acid number, (x) viscosity, and (xi) water content. There are other test methods (such as, for example, the yield of carbon residue) designated necessary to understand properties and behavior of the crude oil under examination.

An inspection assay usually involves determination of several key bulk properties of the feedstock and the products (e.g., API gravity, sulfur content, pour point, and distillation range) as a means of determining if major changes in characteristics have occurred since the last comprehensive assay was performed. For example, a more detailed inspection assay might consist of the following tests: API gravity (or density or relative density), sulfur content, pour point, viscosity, salt content, water and sediment content, trace metals (or organic halides). The results from these tests with the archived data from a comprehensive assay provide an estimate of any changes that have occurred in the crude oil that may be critical to refinery operations. Inspection assays are routinely performed on all crude oils received at a refinery. The inspection assay tests discussed above are not exhaustive but are the ones most commonly used and provide data on the impurities present as well as a general idea of the products that may be recoverable. Other properties that are determined on an as needed basis include, but are not limited to, the following: (i) the vapor pressure (Reid method) for fuels, (ii) the total acid number, and (of somewhat lesser importance for many feedstocks and products) the aniline point (or mixed aniline point).

The *Reid vapor pressure* test method is a measure of the vapor pressure of volatile materials and differs from the true vapor pressure of the sample due to some small sample vaporization and the presence of water vapor and air in the confined space. The *acid number* is the quantity of base, expressed in milligrams of potassium hydroxide per gram of sample that is required to titrate a sample in this solvent to a green/green-brown end point, using p-naphtholbenzein indicator solution. The *strong acid number* is the quantity of base, expressed as milligrams of potassium hydroxide per gram of sample, required to titrate a sample in the solvent from its initial meter reading to a meter reading corresponding to a freshly prepared non-aqueous acidic buffer solution or a well-defined inflection point as specified in the test method. The *aniline point* (or *mixed aniline point*) is more applicable to pure hydrocarbon derivatives and is used to estimate the aromatic content of mixtures. Aromatic mixtures exhibit the lowest aniline points, and paraffin mixtures have the highest aniline points. Cycloparaffin derivatives and olefin derivatives exhibit values between these two extremes.

Therefore, the judicious choice of a feedstock to produce any given product (or products) is just as important as the selection of the product for any given purpose. Indeed, careful evaluation of the feedstock from physical property data is a major part of the initial study of any feedstock destined for conversion to produce a variety of products. Proper interpretation of the data resulting from the inspection of the feedstock (and the products) requires an understanding of the data from the test methods. In the following sections, an indication of the physical properties that may be applied to biomass feedstocks and process products is presented.

Boiling Point Distribution

Boiling range distribution data are used (i) to assess product quality before upgrading to a suitably sales product before purchase, (ii) to monitor product quality during transportation, (iii) to evaluate the product prior to upgrading, and (iv) to provide information for the optimization of the upgrading processes.

Traditionally, boiling range distributions of the various process products have been determined by distillation. Yield-on-feedstock data are still widely reported, thereby providing information on the yield of specific fractions obtained by distillation. To some extent in the laboratory, atmospheric and vacuum distillation techniques have largely been replaced by *simulated* distillation methods, which use low-resolution gas chromatography and correlate retention times to hydrocarbon boiling points.

From the point of view of feedstock and product analysis for environmental purposes, boiling range distributions provide an indication of volatility and component distribution. In addition, boiling range distribution data is also useful for the development of equations for predicting evaporative loss.

Density, Specific Gravity, and API Gravity

Density is the mass per unit volume of a substance. It is most often reported for oils in units of g/mL or g/cm³, and less often in units of kg/m³. Density is temperature-dependent. It is an important property of feedstocks and their respective products by providing the investigator(s) indications of whether or not the contaminant(s) will float on water or sink to the base of any water system.

Two density-related properties of feedstocks products are often used: (i) specific gravity and for fuels, (ii) the American Petroleum Institute (API) gravity. Specific gravity (*relative density*) is the ratio, at a specified temperature, of the feedstock and/or the product density to the density of pure water. The API gravity scale (presented as °API) arbitrarily assigns an API gravity of 10° to pure water. Thus:

$$^{\circ}\text{API} = [141.5/(\text{specific gravity at } 15.6^{\circ}\text{C}) - 131.5]$$

Typically, many organic feedstocks and products will float on water if the density of the material is less than that of the water. This behavior is typical of all crude oils and distillate products for both salt and fresh water.

Emulsion Formation

A water-in-oil emulsion is a stable dispersion of small droplets of water in oil, and when formed, these emulsions can have different characteristics from the parent crude feedstocks (if the feedstocks are liquid). This has important implications for the fate and behavior of any spilled products and any subsequent cleanup. It is desirable, therefore, to determine if the product is likely to form an emulsion, and if so, whether that emulsion is stable, and the physical characteristics of the emulsion.

However, it must be recognized that once spilled, the properties may be changed because emulsion formation and behavior are influenced by the oxidation of product constituents. The inclusion of polar functions such as hydroxyl groups (-OH) or carbonyl groups (>C=O) (a result of the oxidation process) causes an increase in the density of the emulsion (relative to the original unoxidized material) and with an increased propensity to form emulsions. As a result, the emulsion and sinks to various depths or even to the bottom of the water system, depending on the extent of the oxidation and the resulting density. This may give the erroneous appearance (leading to erroneous deductions with catastrophic consequences) that the spill (as evidenced from the material remaining on the surface of the water) is less than it actually was. The so-called *missing* product will undergo further chemical changes and eventually reappear on the water surface or on a distant shore.

Evaporation

Evaporation is the removal of the lower-boiling constituents from a product usually under ambient conditions or, in the current context, under the conditions prevalent at the spill site.

The evaporation rate and loss are of importance for all volatile constituents of the products of thermal and catalytic processes. While standard test methods such as those designated for distillation and vapor pressure determination are often used to determine evaporation properties, test methods for determining evaporation loss are available for higher-boiling products. Although not necessarily applicable to process products in general, evaporation loss data can be obtained at any temperature in the range from 93 and 316°C (200 and 600°F). Viscous samples can be analyzed using a water vaporizer accessory that heats the sample in the evaporation chamber, and the vaporized water is carried into the Karl Fischer titration cell by a dry inert carrier gas.

It must also be recognized that as evaporation occurs, the density and viscosity of the residual product increase, thereby causing behavioral changes in the contaminant. Such changes could be reflected in an increase in adhesion of the contaminant constituents to the soil or rock.

Fire Point and Flash Point

The *fire point* is the lowest temperature, corrected to one atmosphere pressure (14.7 psi), at which the application of a test flame to a sample of a process product causes the vapor of the oil to ignite and burn for at least five seconds.

At any time after a spill of a product, fire should always be considered an imminent hazard. Related to fire point, the flash point is a measure of the tendency of the product to form a flammable mixture with air under controlled laboratory conditions. It is only one of a number of properties that should be considered in assessing the overall flammability hazard of a spilled material.

The ignition temperature (sometimes called the *autoignition temperature*) is the minimum temperature at which the material will ignite without a spark or flame being present.

Also related to fire point, the flammability limits of vapor in air are an expression of the percent concentration in air (by volume) is given for the lower and upper limit. These values give an indication of relative flammability. The limits are sometimes referred to as *lower explosive limit* (LEL) and *upper explosive limit* (UEL).

The *flash point* of a product is the temperature to which the sample must be heated to produce a vapor/air mixture above the liquid fuel that is ignitable when exposed to an open flame under specified test conditions. Furthermore, the flash point is used as an index of fire hazard and is an extremely important factor in relation to the safety of spill cleanup operations. Low-boiling liquid fuels (from whatever the source) can be ignited under most ambient conditions and therefore pose a serious hazard when spilled.

Fractionation

Rather than quantifying a complex total feedstock or product mixture in the form of a single number, fractionation methods break the mixture into discrete fractions, thus providing data that can be used in a risk assessment and in characterizing product type and compositional changes such as may occur during weathering (oxidation). The fractionation methods can be used to measure both the volatile constituents and the extractable constituents.

In contrast to traditional methods that report a single concentration number for complex mixtures, the fractionation methods report separate concentrations for discrete aliphatic and aromatic fractions. The available methods are GC-based and are thus sensitive to a broad range of hydrocarbons. Identification and quantification of aliphatic

and aromatic fractions allows one to identify products and evaluate the extent of product weathering. These fraction data also can be used in risk assessment.

Metals Content

Metals content in a feedstock or related product (especially in the case of biomass feedstocks and the related products) can provide valuable information in identifying the source of a spill as well as the potential for problems during upgrading these materials. Oil spills.

Feedstock and product assays should always include the presence and content of various metals due to the detrimental effects of metals on catalysts used in cracking and desulfurization processes.

Molecular Weight

The molecular weight (formula weight) of a compound is the sum of the atomic weights of all the atoms in a molecule and can be determined by a variety of methods. Fuels (from whatever the source) are complex mixtures of (at least) several hundred constituents requires qualification of the molecular weight as either (i) number average molecular weight or (ii) weight average molecular weight.

The *number average molecular weight* is the ordinary arithmetic mean or average of the molecular weights of the individual constituents. It is determined by measuring the molecular weight of n molecules, summing the weights, and dividing by n . On the other hand, the *weight average molecular weight* is a way of describing the molecular weight of a complex mixture even if the molecular constituents are not of the same type and exist in different sizes. Molecular weight is often used in refineries to provide mass-average or number-average measurements. Consequently, a number of methods are available to measure the molecular weight of feedstocks and products.

If the molecular weight determination involves the use of a solvent, it is recommended that to negate concentration effects and temperature effects, the molecular weight determination be carried out at three different concentrations at three different temperatures. The data for each temperature are then extrapolated to zero concentration, and the zero concentration data at each temperature are then extrapolated to room temperature.

Furthermore, each method of molecular weight determination has proponents and opponents because of assumptions made in the use of the method or because of the mere complexity of the sample and the nature of the inter- and intra-molecular interactions. Also, indirect methods have been proposed for the estimation of molecular weight by correlation with other, more readily measured physical properties. They are satisfactory when dealing with the conventional type of crude oils or their fractions and products when approximate values are desired.

Pour Point

The pour point of a feedstock or a related product is the lowest temperature at which the feedstock (or product) will flow, under standard test conditions. The failure to flow at the pour point is usually attributed to the separation of waxes from the feedstock or the product but can also be due to the effect of viscosity in the case of very viscous materials. Also, the pour point may be influenced by the thermal history of the sample, that is, the degree and duration of heating and cooling to which the sample has been exposed.

Sulfur Content

The sulfur content of a material is important for a number of reasons. Downstream processes such as catalytic cracking and refining will be adversely affected by a high sulfur contents. If high sulfur oils are burned, they produce high levels of sulfur dioxide which can lead to acid deposition (acid rain).

The total sulfur content of material can be determined by numerous standard techniques, and the methods are applicable to both volatile and non-volatile feedstocks and products.

Surface Tension and Interfacial Tension

Interfacial tension is the force of attraction between the molecules at the interface of two fluids. At the air/liquid interface, this force is often referred to as surface tension. The surface tension of a material, together with the viscosity, affects the rate at which a spilled material will spread. Air/oil and oil/water interfacial tensions can be used to calculate a spreading coefficient which gives an indication of the tendency for the oil to spread and which is defined as:

$$\text{Spreading coefficient} = S_{\text{WA}} - S_{\text{OA}} - S_{\text{WO}}$$

S_{WA} is water/air interfacial tension, S_{OA} is oil/air interfacial tension, and S_{WO} is water/oil interfacial tension. Unlike density and viscosity, which show systematic variations with temperature and degree of evaporation, interfacial tensions of many biomass-derived feedstocks and products may not show such correlations.

Total Acid Number

No matter what the source of the fuel, but especially when the fuel is produced directly from biomass, there is a risk that the fuel may have acidic constituents which can have an adverse effect on the performance of the fuel and cause corrosion in the system. The acidic properties of any fuel can be determined by a test method that determines such constituents. The test data are presented as the total acid number. The total acid number (TAN) represents a composite of acids present in the feedstock or the fuel and is often also expressed as the neutralization number.

In the test method, the sample normally dissolved in a solvent (such as toluene/is-propyl alcohol/water) is titrated with potassium hydroxide and the results are expressed as milligrams of potassium hydroxide per gram of sample (mg KOH/gm). Feedstocks and fuels having high acid numbers have a high potential to cause corrosion problems in equipment, especially in the atmospheric and vacuum distillation units where there may also be water present and the hot material comes into contact with hot metal surfaces. Crude oil typically has a total acid number (TAN value) on the order of 0.05 to 6.0 mg KOH/gm of sample.

The impact of corrosive, high TAN, feedstocks and fuels can be overcome by blending higher and lower TAN feedstocks or fuels, installing or retrofitting equipment with anticorrosive materials, or by developing low-temperature catalytic de-acidification processes using metal catalysts such as copper.

Viscosity

Viscosity is a measure of the resistance of a fluid to flow – the lower the viscosity of a fluid, the more easily it flows. Like density, viscosity is affected by temperature. As temperature decreases, viscosity increases. Viscosity is an important property of feedstocks and products because it affects (i) the rate at which a spilled material will spread, (ii) the degree to which the spilled material will penetrate shoreline substrates, and (iii) the selection of mechanical spill countermeasures equipment.

Viscosity measurements may be absolute or relative – the latter is sometimes called apparent viscosity. Absolute viscosity is measured by a standard method, with the results traceable to fundamental units. The absolute viscosity is distinguished from the relative viscosity that is made with instruments that measure viscous drag in a fluid, without known and/or uniform applied shear rates. An important benefit of absolute viscometry is that the test results are independent of the particular type or make of viscometer used and the absolute viscosity data can be compared easily between laboratories worldwide.

Water Content

Some of the feedstocks and products produced from alternative energy sources may contain substantial amounts of water. Therefore, for materials with significant water contents, (>5% w/w), many of the properties measured will not represent the properties of the *dry* material.

Water content has not been conclusively identified as a direct governing environmental factor in the biodegradation of spilled materials, but an indirect effect of water content is that it influences the effective gas diffusion coefficient in soils. The rate of production of carbon dioxide is a means of expressing the mineralization rate of spilled products.

Product Analysis – Chromatographic Methods

Product analyses are conducted to determine the amounts of the compound classes present in many feedstocks and products. This type of measurement is sometimes used to identify fuel type or to track plumes. It may be particularly useful for higher-boiling products. Group type test methods include multidimensional gas chromatography

(not often used for environmental samples), high performance liquid chromatography (HPLC), and thin layer chromatography.

Common constituent measurement techniques include gas chromatography with second column confirmation, gas chromatography with multiple selective detectors, and gas chromatography with mass spectrometry detection (GC/MS).

Gas Chromatography

Gas chromatography (GC), which is based on the principle of a stationary phase and a mobile phase, remains a primary technique for determining constituents distribution in many feedstocks and products through the identification of individual constituents. Although a measure of purity by gas chromatography is often sufficient for many purposes, it is not always sufficient for measuring absolute purity – not all possible impurities will pass through the chromatographic column, and not all those that do will be measured by the detector. Absolute purity is best measured by distillation range or freeze or solidification points. Despite this disadvantage, the technique is still widely used and is the basis of many current standard test methods for the determination and measurement of the constituents in many process feedstocks and products.

Gas-liquid chromatography (GLC) is a method for separating the volatile components of various mixtures. It is, in fact, a highly efficient fractionating technique, and it is ideally suited to the quantitative analysis of mixtures when the possible components are known and the interest lies only in determining the amounts of each present. In this type of application, gas chromatography has taken over much of the work previously done by the other techniques; it is now the preferred technique for the analysis of hydrocarbon gases, and gas chromatographic in-line monitors are having increasing application in refinery plant control. Gas-liquid chromatography is also used extensively for individual component identification, as well as percentage composition, in the gasoline boiling range.

The mobile phase is the carrier gas, and the gas selected has a bearing on the resolution. Nitrogen has poor resolution ability, while helium and hydrogen are better choices with hydrogen being the best carrier gas for resolution. However, hydrogen is reactive and may not be compatible with all sets of target analytes. There is an optimum flow rate for each carrier gas to achieve maximum resolution. As the temperature of the oven increases, the flow rate of the gas changes due to thermal expansion of the gas. Most modern gas chromatographs are equipped with constant flow devices that change the gas valve settings as the temperature in the oven changes, so changing flow rates are no longer a concern. Once the flow is optimized at one temperature, it is optimized for all temperatures.

Gas Chromatography-Mass Spectrometry

A gas chromatography-mass spectrometry system is used to measure concentrations of the target volatile and semi-volatile of the sample. The advantage of the technique is the high selectivity, or the ability to confirm compound identity through retention time and a unique spectral pattern. The method is used for identification and quantification of the constituents of feedstocks and products.

To reduce the possibility of false positives, the intensities of one-to-three selected ions are compared to the intensity of a unique target ion of the same spectrum. The sample ratios are compared to the ratios of a standard. If the sample ratios fall within a certain range of the standard, and the retention time matches the standard within specifications, the analyte is considered present. Quantification is performed by integrating the response of the target ion only.

Mass spectrometers are among the most selective detectors, but they are still susceptible to interferences. Isomers have identical spectra, while many other compounds have similar mass spectra. Feedstocks and products may contain thousands of major components that are not resolved by the gas chromatograph. As a result, multiple compounds are simultaneously entering the mass spectrometer. Different compounds may share many of the same ions, confusing the identification process. The probability of misidentification is high in complex mixtures.

High-Performance Liquid Chromatography

A high-performance liquid chromatography system can be used to measure concentrations of target semi-volatile and non-volatile constituents of mixtures. The system only requires that the sample be dissolved in a solvent compatible with those used in the separation. The detector most often used in environmental analysis is the fluorescence

detector. These detectors are particularly sensitive to aromatic molecules, especially polynuclear aromatic hydrocarbons. An ultraviolet detector may be used to measure compounds that do not fluoresce.

Interfering compounds will vary considerably from source to source, and samples may require a variety of clean-up steps to reach the required method detection limits. The emission wavelengths used (EPA 8310) are not optimal for the sensitivity of the small ring compounds. With a modern electronically-controlled monochromator, wavelength programs can be used which tune excitation and emission wavelengths to maximize sensitivity and/or selectivity for a specific analyte in its retention time window.

Thin Layer Chromatography

In the environmental field, thin layer chromatography (TLC) is best used for screening analyses and characterization of semi-volatile and non-volatile materials. The precision and accuracy of the technique is inferior to other methods, but when speed and simplicity are desired, thin layer chromatography may be a suitable alternative. For characterizations of high-boiling constituents, the method has the advantage of separating compounds that are too high boiling to pass through a gas chromatograph. While thin layer chromatography does not have the resolving power of a gas chromatograph, it is able to separate different classes of compounds. Thin layer chromatography analysis is fairly simple and, since the method does not give highly accurate or precise results, there is no need to perform the highest-quality extractions.

The method is considered to be a qualitative and useful tool for rapid sample screening. Limitations of the method center on its moderate reproducibility, detection limits, and resolving capabilities. Variability between operators can be as high as 30%. It is often not possible to distinguish between similar products, and, as with all chemical analyses, quality assurance tests should be run to verify the accuracy and precision of the method.

Product Analysis – Spectroscopic Methods

The chemical composition of a feedstock has always been considered to be a valuable indicator of refining behavior. Whether or not it is the ultimate indicator of refining behavior remains to be seen and is audience dependent! More than likely, chemical composition studies truly complement physical property and physical behavior studies and the true picture is a combination of all of these studies.

However, the chemical composition of a feedstock is represented in terms of compound types and/or in terms of generic compound classes, thus allowing the analytical chemist, the process chemist, the process engineer, and the refiner to determine the nature of the reactions. Hence, chemical composition can play a large part in determining the nature of the products that arise from the refining operations. It can also play a role in determining the means by which a particular feedstock should be processed. However, proper interpretation of the data resulting from the composition studies requires an understanding of chemical structures, their significance, and an open mind!

The physical and chemical characteristics of feedstocks and the yields and properties of products or factions prepared from them vary considerably and are dependent on the concentration of the various types of hydrocarbons and minor constituents present. Some types of biomass-related feedstocks have economic advantages as sources of fuels with highly restrictive characteristics because they require less specialized processing than that needed for production of the same products from many types of feedstocks. Others may contain unusually low concentrations of components that are desirable fuel or lubricant constituents, and the production of these products from such crude oils may not be economically feasible.

Spectroscopic studies have played an important role in the evaluation of feedstocks and their respective products for the last six decades, and many of the methods are now used as standard methods of analysis for refinery feedstocks and products.

Infrared Spectroscopy

Infrared spectroscopy is a well-established method that was developed for comparative, semi-quantitative analysis leading to the present quantitative analysis. Infrared spectra are displayed either as percent transmittance or as absorptivity versus frequency (cm^{-1}). Transmittance, T , defined as the ratio of transmitted light over incident light, or percent transmittance, usually shows more detail over the entire range and is generally the preferred display.

Absorbance, A , on the other hand, is proportional to the concentration and is, therefore, used for quantitative measurements.

In combination with nuclear magnetic resonance spectroscopy, infrared spectroscopy is a simple procedure and is one of several techniques that can provide quick information about the distribution of several structural and functional groups. However, in the context of high-molecular-weight constituents, conventional infrared spectroscopy yields information about the functional features of various feedstock and product constituents. For example, infrared spectroscopy will aid in the identification of imino functions ($=N-H$) and hydroxyl ($-O-H$) functions, as well as the nature of the various carbonyl ($-C=O$) functions.

With the more recent progress of *Fourier transform infrared (FTIR) spectroscopy*, quantitative estimates of the various functional groups can also be made. This is particularly important for application to the higher-molecular-weight solid constituents of feedstock and products and for group-type analysis. Also, the newer diffuse reflectance infrared (DRIR) techniques seem to give equally good spectra as obtained in conventional ways from solutions in cells or from potassium bromide (KBr) pellets. Another synonym for this technique is DRIFT (for diffuse reflectance infrared Fourier transform).

Band assignments for infrared spectra were established several decades ago. Resolution enhancement by Fourier self-deconvolution (band narrowing) led to the recognition and distinction of bands that could previously not be separated. Examples of such new assignments are methyl (CH_3) groups next to aromatic rings ($2,948\text{ cm}^{-1}$) and next to alkyl groups ($2,960\text{ cm}^{-1}$), methylene (CH_2) groups (together with some methyl groups) next to aromatic rings ($2,916\text{ cm}^{-1}$) and in aliphatic chains ($2,926\text{ cm}^{-1}$), methylene groups next to an alkoxy function ($2,928\text{ cm}^{-1}$) and next to a carbonyl group ($2,933\text{ cm}^{-1}$); and methane (CH) groups in unspecified environments ($2,905\text{ cm}^{-1}$ and $1,897\text{ cm}^{-1}$). The rocking vibration band of methylene groups in straight aliphatic chains varies slightly with their length. For n -pentyl groups, it is located at 726 cm^{-1} , and with longer chains, it shifts to lower frequencies until it stabilizes at 720 cm^{-1} for chains with more than nine carbon atoms.

Mass Spectrometry

Mass spectrometry furnishes the molecular weight and chemical formula of compounds and their relative amounts in a mixture and offers a non-destructive examination of the sample. The technique can also provide important information about their molecular structure. The earliest and most common type of mass spectrometry, electron impact mass spectrometry (EI-MS), gives a fragmentation pattern displaying both parent ion peaks and fragment ion peaks, characteristic of each molecular type.

Fragmentation is frequently employed to differentiate between isomers of pure compounds and of molecules in fairly simple mixtures. However, it is usually avoided with such complex samples as high-molecular-weight materials, which are composed of such a multitude of closely related compounds that their fragmentation patterns are non-distinctive and cannot be readily interpreted.

Mass spectrometry can play a key role in the identification of the constituents of feedstocks and products either in the laboratory or online. The principal advantages of mass spectrometric methods are (i) high reproducibility of quantitative analyses, (ii) the potential for obtaining detailed data on the individual components and/or carbon number homologues in complex mixtures, and (iii) a minimal sample size is required for analysis. The ability of mass spectrometry to identify individual components in complex mixtures is unmatched by any modern analytical technique. Perhaps the exception is gas chromatography.

However, there are disadvantages arising from the use of mass spectrometry and these are: (1) the limitation of the method to organic materials that are volatile and stable at temperatures up to 300°C (570°F); and (2) the difficulty of separating isomers for absolute identification. The sample is usually destroyed, but this is seldom a disadvantage. Nevertheless, in spite of these limitations, mass spectrometry does furnish useful information about the composition of feedstocks and products even if this information is not as exhaustive as might be required. There are structural similarities that might hinder identification of individual components. Consequently, identification by type or by homologue will be more meaningful since similar structural types may be presumed to behave similarly in processing situations. Knowledge of the individual isomeric distribution may add only a little to an understanding of the relationships between composition and processing parameters.

High-voltage electron impact mass spectrometry (HVEI-MS or EI-MS) can cause repeated fragmentation of daughter ions. Considering the repeated fragmentation of even the simplest hydrocarbons and the fact that the

higher-molecular-weight fractions of feedstocks and products may contain such a broad range of molecular weight species, the patterns obtained from these types of materials are so complex as to almost defy interpretation. Thus, non-fragmenting mass spectrometric methods are preferred.

For high-molecular-weight feedstocks and products, the use of non-fragmenting mass spectrometry (NF-MS) methods is now preferred. These methods, also called *soft ionization* methods, produce predominantly parent ion (molecular ion) peaks and, thus, much simpler spectra than methods producing fragments. By rendering the molecular weight of each compound in a sample, and reasonably well its abundance, non-fragmenting mass spectrometry also can be used to determine the molecular weight distribution, i.e., the molar mass profile of a sample.

Indeed, the great advantage of *non-fragmenting mass spectrometry* is the relative simplicity of the spectra. A disadvantage is the relatively low signal intensity of the ions. With *low-voltage electron impact ionization*, the number of parent ions formed increases rapidly as the ionizing voltage increases above the ionizing potential of the molecules in the sample. Thus, a higher voltage gives a more intense signal (up to about 20-40 eV, depending on compound type). However, the higher ionizing voltage transfers more energy to the sample molecules and causes fragmentation to increase. The surplus energy transferred to the molecule in excess of the ionizing potential is equilibrated and dissipated in various ways, for example, by increasing the internal energy of the molecule or by breaking atomic bonds.

Among the most important non-fragmenting mass spectrometric techniques are field ionization mass spectrometry (FIMS), field desorption mass spectrometry (FDMS), chemical ionization mass spectrometry (CIMS), and low-voltage (10-20 eV) electron impact mass spectrometry (LVEI-MS). A particularly powerful version of electron impact mass spectrometry is high-resolution electron impact mass spectrometry (HR-LEVI-MS or LVRH-MS). All of these are designed to generate *cold* ions of such low excess energy that they do not undergo fragmentation to any great extent, in contrast to the *hot* ions generated by conventional electron impact ionization (70 to 100 eV). With such ionization methods, a compromise must be found between low fragmentation and sufficiently high sensitivity. Unfortunately, samples rich in aliphatic hydrocarbons are hard to keep completely from fragmenting, but most other compound types, especially aromatic compounds, yield clean parent ion spectra.

Field ionization mass spectrometry shows extremely low fragmentation because the ionization process imparts little excess energy to the formed ion. This is crucial when ionizing saturates. Both low-voltage electron impact (LVEI) and chemical ionization (CI) transfer more excess energy than field ionization mass spectrometry, leading to higher levels of fragmentation with saturates. As long as the analyte is volatile, the field ionization mass spectrometry experiment is not sample limited. That is, additional sample can be vaporized as needed to obtain the required signal-to-noise ratio. Field desorption mass spectrometry (FDMS) can be considered a special form of electron impact mass spectrometry (EIMS) where the sample material is placed on the ionizing surface of the probe before insertion into the sample chamber of the mass spectrometer. It is, however, sample limited and subject to experimental artifacts not normally present in electron impact mass spectrometry.

In the electron impact mass spectrometry technique, the emitting surface is a cathode consisting of an array of sharp tips on a support such as a wire, a grid, or a razor blade. This surface is located close to the anode. The combination of an extremely small radius of curvature of the tips, the short distance, and the high electric field creates a high field gradient. The sample is introduced to this field gradient by evaporation and diffusion from a heated surface nearby.

Field desorption mass spectrometry is a special form of field ionization mass spectrometry. The cathode is the same, but here it is coated with the sample before it is placed in the mass spectrometer source. This eliminates the need to evaporate the sample and any losses on transport to the cathode. Instead, the ions are desorbed directly from the solid sample. The emitter is heated to the point where the sample melts and can be drawn by the surface tension to the tip where the molecules are converted to ions. As the ions are ejected from the surface into the mass spectrometer, more sample molecules can replace them at the tip. In this way, labile molecules can be handled without significant fragmentation, and even conventionally nonvolatile samples can be run. Thus, the method is especially suitable for the high-molecular-weight fractions of non-volatile materials. Because of the low thermal energy to which the sample molecules are exposed, the total excess energy in this process is minimal. Thus, field desorption mass spectrometry is an even milder method than field ionization mass spectrometry and produces less fragmentation.

Chemical ionization mass spectrometry (CI-MS), another *soft* method, has been used only occasionally for non-volatile with mixed success. In the method, a relatively high-pressure reagent gas (e.g., methane, *n*-butane, *iso*-butane) is ionized and allowed to contact the sample. At such pressures, the reagent ions undergo many collisions

that help them lose excess energy left after ionization. The ions also exchange charges during collision with one another and with the sample molecules. The latter is the desired reaction, and the method works best when the sample molecules retain the charge better than the reagent molecules.

Fast atom bombardment mass spectrometry (FAB-MS) is a method in which the sample is dissolved in a high-boiling polar liquid matrix (such as glycerol or triethanolamine) and spread on a plate. Rare gas molecules (e.g., xenon or argon) are ionized, accelerated, focused at the sample, and stripped of their charge before they hit their target. The impact of uncharged atoms sputters small amounts of the matrix and sample off the sample plate. The liquid matrix evaporates, liberating charged sample ions, which are now propelled by the accelerating voltage into the mass spectrometer.

Nuclear Magnetic Resonance

Nuclear magnetic resonance has frequently been employed for general studies of hydrogen types in feedstocks and products. The technique has recently been adapted to measure the hydrogen content of fuels and, in fact, *proton magnetic resonance* (PMR) studies (along with infrared spectroscopic studies) were, perhaps, the first studies of the modern era that allowed structural inferences to be made about the polynuclear aromatic systems that occur in the high-molecular-weight constituents of feedstocks and products.

The technique presents a direct measure of the aromatic and aliphatic carbon as well as hydrogen distribution. Beyond these results, both carbon and hydrogen in various structural groupings in a molecule can be determined. Thus, proton (^1H) and carbon-13 (^{13}C) nuclei are the most common ones used in nuclear magnetic resonance spectroscopy; nitrogen (^{15}N and ^{14}N) and sulfur (^{33}S) have been employed on occasion for special applications.

Only a small amount (<10 mg) of the sample is required, dissolved in a solvent such as deuterio-chloroform, contained in a glass tube of 5 mm diameter and placed in a highly homogeneous magnetic field where it is surrounded by one or more coils. The coils serve to subject the sample to a weak radio-frequency (RF) field. The hydrogen nuclei of the sample can be visualized as magnets, and when the radio frequency is equal to the processing frequency, resonance occurs between the two, and the spin resonance is detected by a receiver coil. The position of a sample resonance with that of tetramethylsilane (TMS) as a reference difference is reported as *chemical shift*, δ , which is a dimensional number that is expressed in terms of parts per million (ppm) difference from the reference (TMS).

Carbon-13 magnetic resonance (CMR) can play a useful role. Since carbon magnetic resonance deals with analyzing the carbon distribution types, the obvious structural parameter to be determined is the aromaticity, f_a . A direct determination from the various carbon-type environments is one of the better methods for the determination of aromaticity. Thus, through a combination of proton and carbon magnetic resonance techniques, refinements can be made on the structural parameters and, for the solid state high resolution CMR technique, additional structural parameters can be obtained.

Thus, proton and carbon-13 magnetic resonance spectroscopic techniques offer the potential information about the molecular types in the non-volatile fractions of feedstocks and products. The techniques have, by the application of the estimation of peak areas and further application of mathematical methods, been used to obtain information about *structural parameters* that are then converted to *average structures*.

Ultraviolet Spectroscopy

The ultraviolet-visible (UV-Vis) spectrum, although not as specific for chemical group types as is infrared spectroscopy and nuclear magnetic resonance spectroscopy, can distinguish between aromatic compounds with different ring numbers and configurations. The patterns are not distinct enough to recognize or distinguish these compounds in complex mixtures, but they can be useful for their identification in narrow fractions.

Ultraviolet-visible spectroscopy can be employed as a detector for the fractionation of various samples, for example, for the chromatographic separation and/or identification of aromatics by ring number, especially in combination with a technique such as liquid chromatography. Thus, ultraviolet-visible spectroscopy lends itself to studies of refining processes as an online detector.

X-Ray Diffraction

X-ray diffraction had been used for the determination of the fraction of aromatic carbon (f_a) in feedstocks and, in some cases, products. This ratio can also be conveniently and precisely obtained by carbon-13 nuclear magnetic

resonance spectroscopy as well as by infrared spectroscopy. The determination of the fraction of carbon that is aromatic may be in error since X-ray diffraction data can be very misleading, especially when the data are used to translate geometric data – measurements of (aromatic) sheet diameter – into structural information. On the one hand, not all aromatic atoms contribute to the stack diameter seen by x-ray diffraction whereas, on the other hand, non-aromatic atoms such as hydroaromatic carbons and other substituents on aromatic rings may contribute to the diffraction pattern. Thus, the interpretation of these measurements is quite arbitrary.

Extended x-ray absorption fine structure (EXAFS) and *x-ray absorption near-edge structure* (XANES) spectroscopy are tools for the investigation of the immediate chemical environment of x-ray absorbing elements such as metals and sulfur. X-ray absorption near-edge structure and x-ray photoelectron spectroscopy (XPS) have been applied to the determination of sulfur compounds in samples.

Product Blending

The modern crude oil refinery consists of a complex mix of high technology processes which efficiently convert the wide array of crude oils into the hundreds of specification products that are in daily use. Each refinery has its own unique processing configuration as a result of the logistics and associated economics related to its specific crude oils and products markets. The refiner must continuously optimize the mix of product volumes, and this is accomplished through executing decisions regarding parameters as varied as crude oil feedstock selection, adjustments in product cut-points, and reactor severities in individual processes. Additional options include changing the dispositions of intermediate product streams to alternative processing units, or alternative finished product blends.

In fact, many refinery products are typically the result of blending several component streams or blending stocks. In most cases, product blending is accomplished by controlling the volumes of blend stocks from individual component storage tanks that are mixed in the finished product storage tank. Samples of the finished blend are then analyzed by laboratory testing for all product specifications prior to shipping. Alternatively, in-line blending refers to pipeline shipments in which the finished product is actually blended directly into the product pipeline (as opposed to a standing product storage tank).

The most commonly recognized blending operations occur in the gasoline production section of the refinery. The various gasoline streams are so that specifications (dependent upon geographic location, environmental regulations, and weather patterns) can be met.

Gasoline blending involves combining of the components that make up motor gasoline. The components include the various hydrocarbon streams produced by distillation, cracking, reforming, and polymerization, tetraethyl lead, and identifying color dye, as well as other special-purpose components, such as solvent oil and anti-icing compounds. The physical process of blending the components is simple, but determination of how much of each component to include in a blend is much more difficult. The physical operation is carried out by simultaneously pumping all the components of a gasoline blend into a pipeline that leads to the gasoline storage, but the pumps must be set to automatically deliver the proper proportion of each component. Baffles in the pipeline are often used to mix the components as they travel to the storage tank.

Selection of the components and their proportions in a blend is the most complex problem in a refinery. Many different hydrocarbon streams may need to be blended to produce quality gasoline. Each property of each stream is a variable, and the effect on the product gasoline is considerable. For example, the low octane number of straight-run naphtha limits its use as a gasoline component, although its other properties may make it desirable. The problem is further complicated by changes in the properties of the component streams due to processing changes. For example, an increase in cracking temperature produces a smaller volume of higher octane cracked naphtha, but before this cracked naphtha can be included in a blend, adjustments must be made in the proportions of the other hydrocarbon components. Similarly, the introduction of new processes and changes in the specifications of the finished gasoline dictate reevaluation of the components that make up the gasoline.

Gasoline blending is not the only blending operation; other product blending operations are also in operation in a refinery. The applicable specifications vary by product but typically include properties pertinent to the behavior of the product in use. Many product specifications do not blend linearly by component volumes. In these

circumstances, the finished blend properties are predicted using experience-based algorithms for the applicable blending components.

Product Improvement

From a chemical standpoint, fuels produced from alternate feedstocks are complex mixtures of hydrocarbon compounds, usually with minor amounts of nitrogen-, oxygen-, and sulfur-containing compounds as well as trace amounts of metal-containing compounds.

For the purposes of terminology, it is preferable to subdivide crude oil and related biomass liquids materials into three major classes which are: (i) materials that are of natural origin, (ii) materials that are manufactured, and (iii) materials that are integral fractions derived from the natural or manufactured products.

The materials included in categories 1 and 2 are relevant here because of their participation in product streams. Straight-run constituents of crude oil (i.e., constituents distilled without change from crude oil) are used in products. Manufactured materials are produced by a variety of processes and are also used in product streams. Category 3 materials are usually those materials that are isolated from crude oil or from a product by the use of a variety of techniques.

The production of liquid product streams by distillation or by cracking processes are only the first of a series of steps that lead to the production of marketable liquid products. Several other unit processes are involved in the production of a final product. Such processes may be generally termed *secondary processes* or *product improvement processes* since they are not used directly on the crude oil but are used on primary product streams that have been produced from the crude oil.

In addition, the term product improvement includes processes such as reforming processes in which the molecular structure of the feedstock is reorganized. An example is the conversion (*reforming*, *molecular rearrangement*) of *n*-hexane to cyclohexane or cyclohexane to benzene. These processes *reform* or *rearrange* one particular molecular type to another, thereby changing the properties of the product relative to the feedstock. Such processes are conducive to expansion of the utility of crude oil products and to sales.

Production of Organic Matter in Aqueous Environments

Photosynthesis by phytoplankton, especially blue-green algae (Cyanophyceae), diatoms, dinoflagellates, and in warmer waters by phyto bacteria, is ultimately responsible for producing nearly all of the organic matter in the oceans.

A precise quantitative relationship between the fossil record and organic productivity is not available; many productive species have no hard body parts that are easily preserved. Hence, the productivity may not be reflected in the surviving fossils. Nevertheless, as pointed out by Moore, the fossil record indicates significant differences between production in marine and lacustrine environments.

Photosynthetic productivity is mainly controlled by light, temperature, and nutrient availability. Light seems not to be the controlling factor, except in deep water, Polar Regions, or turbid coastal regions. The availability of carbon dioxide, which is essential for photosynthesis, is not limiting in the *eutrophic zone* (the top 200 meters, or so, where productivity is highest). Rather, nutrient availability – often nitrogen (as ammonium or nitrate) in marine or phosphate in lacustrine, environments seems to be the most common limit on productivity. The availability of vitamins, especially of vitamin B12, and other trace organics is important, and seems to be a limiting factor in some areas. Productivity in lakes follows the same general pattern as in oceans, but deposition in the confines of a lake is much more subject to local climatic variations and periodic changes in clastic input (e.g., volcanic ash) than is marine deposition.

See also: Photosynthesis.

Product Treating

Fractions or streams produced from alternate (non-fossil fuel sources) often contain variable amounts of impurities that must be removed. Processes that remove these undesirable components are known as treating processes, and these processes are used not only to finish products for the market but also to prepare feedstocks for other processes (*catalytic polymerization* and *reforming*) in which catalysts would be harmed by impurities.

The undesirable components in a crude oil fraction are referred to as impurities, but they are almost invariably either the normal constituents of crude oil or they are derivatives of the constituents of crude oil. The most common impurities are sulfur compounds that are derived from the sulfur compounds that occur in crude oil, such as sulfides (R^1SR^2) and the foul-smelling mercaptan derivatives (RSH), also called thiols. Oxygen compounds in the form of carboxylic acid derivatives (RCO_2H) and phenol derivatives ($ArOH$, where Ar is an aromatic group) may also be present. Nitrogen-containing compounds derived from those that occur in crude oil are also present.

Sometimes, olefins ($R^1CH=CHR^2$, R^1 and R^2 may or may not be similar hydrocarbon groups) must be eliminated from a feedstock or aromatics removed from a solvent, and these olefins and aromatics are considered impurities. Similarly, polymerized material, asphaltic material, or resins may be impurities, depending on whether their presence in a finished product is harmful.

During processing, much of the sulfur originally in the crude oil is converted to hydrogen sulfide (H_2S) and mercaptans ($R-SH$). Some sulfur may be retained in any coke that is formed. Processes that are primarily concerned with the removal of hydrogen sulfide and mercaptans are known as *sweetening* processes. Crude oil fractions containing mercaptans are readily recognized by their odor and are called *sour*. Fractions that are free of obnoxious sulfur compounds, either naturally or because of treatment, are called *sweet*, but a sweet fraction may contain sulfur compounds (e.g., sulfide R^1SR^2 or disulfide R^1SSR^2) that have no odor. The more severe desulfurization of crude oil fractions is not usually classed as a treating process, but recognition has been given to processes such as hydrotreating processes and hydrocracking processes that contribute to product improvement.

The need to remove sulfur (desulfurization) from various feedstocks is of significant importance. Thus, desulfurization is a major refinery issue and is worthy of mention here. Indeed, considerable importance has been attached to the lowering of the sulfur level in distillates and residual stocks. For example, the stability of sulfur compounds is greatly reduced when they are heated in the presence of adsorptive catalysts, and this is employed in a number of desulfurization processes. The non-cyclic sulfur compounds (mercaptans, RSH , sulfides, RSR , and disulfides, $RSSR$) in straight-run distillates (such as naphtha) are readily converted into hydrogen sulfide and olefins by contacting the vapors with clays, aluminum oxide, or alumina-silica ($Al_2O_3-SiO_2$) cracking catalysts. These processes generally operate at approximately 345 to 425°C (650 to 800°F) and at a pressure of approximately 50 psi.

When hydrogen is added and a dehydrogenation catalyst, such as cobalt sulfide and molybdenum sulfide on alumina, is employed, extensive desulfurization or denitrogenation of a wider spectrum of heteroatomic compounds is achieved. Even the refractory cyclic nitrogen and sulfur compounds are decomposed, and the heteroatom is released as its hydrogen analog (e.g., H_2S or NH_3).

Treatment processes for the removal of sulfur-containing and nitrogen-containing compounds are much less severe than the desulfurization and denitrogenation processes. In fact, it is generally recognized that the removal or conversion of sulfur and nitrogen compounds in distillates by treatment processes is usually limited to mercaptans and the lower-molecular-weight sulfur compounds. When there is more than a trace amount ($>0.1\%$) of heteroatoms present, it is often more convenient and economical to resort to such methods as those thermal processes (e.g., hydroprocesses) that bring about a decrease in all types of heteroatomic compounds.

Choices of a treatment method depend on the amount and type of impurities in the fractions to be treated and the extent to which the process removes the impurities. Naturally occurring sweet kerosene, for example, may require only a simple treatment with alkali (*lye*) to remove hydrogen sulfide. If mercaptans are also present in the raw kerosene, a doctor treatment in addition to *lye treatment* is required, but poor-quality raw kerosene may require, in addition to these treatments, treatment with sulfuric acid and Fuller's Earth. The lowest quality raw kerosene requires treatment with strong sulfuric acid, neutralization with lye, and redistillation. Since different fractions have the same impurities, the same treatment process may be used for several different products.

There is a choice of several different treatment processes, but the primary purpose of the majority is the elimination of unwanted sulfur compounds. Some processes are limited to the conversion of certain sulfur compounds, as well as olefins, asphaltic materials, oxygen compounds, and nitrogen compounds. The various processes eliminate impurities by chemical reagents, by catalysts, and by adsorption on clays or similar materials. Some chemical treatment processes directly remove sour sulfur compounds and hence tend to supplant the older processes that sweeten by conversion of sulfur compounds. Caustic soda (*lye*) solutions have long been used to remove hydrogen sulfide and some of the lower-boiling mercaptan derivatives. Caustic soda, however, does not remove the higher-boiling mercaptans. By combining caustic soda solution with various solubility promoters (methyl alcohol, cresols, naphthenic acids, and alkyl phenols), up to 99% of all mercaptans as well as oxygen and nitrogen compounds can be dissolved from crude oil fractions.

Sulfuric acid (H_2SO_4) treatment has the longest history of any crude oil-treating method. Sulfuric acid was the preferred treating material for all crude oil fractions from naphtha to lubricating oil for a century and is still widely used. Modern use of sulfuric acid is only a fraction of its former use. Nevertheless, the removal or conversion of mercaptans can be effected by sulfuric acid or by anhydrous aluminum chloride (AlCl_3), but the chemistry of the sulfuric acid desulfurization is not fully understood. Sulfides and disulfides are removed by addition reactions with aluminum chloride or by solution with sulfuric acid. Cyclic sulfides, such as tetramethylene and pentamethylene sulfide as well as sulfones $[\text{R}-\text{S}(=\text{O})-\text{R}]$ and sulfoxides $[\text{R}-\text{S}(\text{O})_2-\text{R}]$, are also removed by solution in the acid.

A number of commonly used treatment processes (doctor treatment, copper chloride treatment, and sodium hypochlorite treatment) convert mercaptans into odorless disulfides, which remain dissolved in the crude oil fraction. If no harm will result from a small amount of disulfides, they may be left in finished products, such as kerosene or stove oil. When sulfur compounds cannot be tolerated, as in solvent naphtha, disulfides are removed in a bottom fraction obtained by redistilling the sweetened naphtha.

Hypochlorite derivatives, for example sodium hypochlorite (NaOCl , bleaching powder), oxidize mercaptans (RSH) to disulfides (RSSR) and alkyl sulfides (thioethers) (RSR) are oxidized to sulfoxides $[\text{RS}(\text{O})_2\text{R}]$. The lower-molecular-weight products may be water-soluble.

Mercaptan derivatives (e.g., $\text{RCH}_2\text{CH}_2\text{SH}$) may also be removed from refinery products in a process in which they are converted to hydrogen sulfide (H_2S) and the corresponding olefin ($\text{RCH}=\text{CH}_2$), either by heat alone or, more easily, in the presence of catalysts such as bauxite (crude alumina, Al_2O_3). However, thioethers may be produced if the catalyst contains zinc sulfide (ZnS) and/or cadmium sulfide (CdS).

Propane

Commercial Propane consists predominantly of propane and/or propylene, while Commercial Butane is mainly composed of butanes and/or butylenes. Both must be free from harmful amounts of toxic or nauseating substances and free from mechanically entrained water. In the case of Commercial Propane, water content may be further limited by specific tests.

Commercial propane-butane mixtures are produced to meet particular requirements and find application as fuels in areas and at times where low ambient temperatures are less frequently encountered. Typical specifications contain clauses covering volatility, vapor pressure, specific gravity, hydrocarbon composition, sulfur and its compounds, corrosion of copper, residues, and water content.

Special Duty Propane is intended for use in spark-ignition engines. In Europe, this demand is often met by the commercial grades described above, but in USA, a tightly controlled C_3 mixture is specified. In addition to the usual clauses, the specification includes a minimum motor octane number to ensure satisfactory antiknock performance. Propylene has a significantly lower octane number than propane, so there is a limit to the amount of this component that can be tolerated in the mixture.

Volatility, vapor pressure, and relative density

The vaporization and combustion characteristics of commercial liquefied gas products are completely defined for normal applications by volatility, vapor pressure, and to a lesser extent, specific gravity. The last by itself has little significance and can only give an indication of quality characteristics when combined with values for volatility

and vapor pressure. It is important for stock quantity calculations and is used in connection with transport and storage. Volatility is expressed in terms of the temperature at which 95% of the material is evaporated. It gives a measure of the least volatile component present. Vapor pressure is related to the more volatile components present. It therefore gives a measure of the most extreme low temperature conditions under which initial vaporization can take place.

By setting limits to vapor pressure and volatility jointly, the specification serves to ensure essentially single-component products for the butane and propane grades. By combining vapor pressure/volatility limits with specific gravity for propane-butane mixtures, essentially two-component systems are ensured.

Hydrocarbon composition

Clauses are included to limit the amounts of minor constituents. These may relate to groups of hydrocarbon derivatives or to specific compounds. Thus limits are set to the total amount of C_2 , C_4 , or C_5 hydrocarbon derivatives and to ethylene in particular, to total dienes and total acetylenes.

By limiting the amount of hydrocarbon derivatives that are lower-boiling than the main component, the vapor pressure control is reinforced. The limitation on the amount of higher-boiling hydrocarbon derivatives supports the volatility clause. The vapor pressure and volatility specifications will often be met automatically if the hydrocarbon composition is correct.

The amount of ethylene is limited for two reasons. Firstly, it may be desirable to restrict the amount of unsaturated components so as to avoid the formation of polymerization deposits. Secondly, the restriction constitutes an additional volatility clause. Ethylene is more volatile than ethane, and therefore, a product with all its C_2 hydrocarbon derivatives in the form of ethylene will have a higher vapor pressure and volatility than one in which the two-carbon constituents are entirely ethane. Both could, however, meet the relevant C_2 clause.

Acetylene is an undesirable constituent because of its corrosive action on copper. A further point, less significant because of the low concentration of acetylene, is that acetylene is more explosive than the other hydrocarbon derivatives present. Butadiene is also undesirable because it may produce deposits that will cause blockages.

Sulfur, sulfur compounds, and corrosion of copper

The following may be defined by a specification: total (volatile) sulfur, carbonyl sulfide, hydrogen sulfide, mercaptan, and copper corrosion.

The manufacturing processes for liquefied petroleum gas are such that most sulfur compounds are removed. The total sulfur level is therefore considerably lower than for other crude oil fuels. A maximum limit for sulfur content helps to define the product more completely. The sulfur compounds that are mainly responsible for corrosion are hydrogen sulfide, carbonyl sulfide, and sometimes elemental sulfur. Hydrogen sulfide and mercaptans have distinctive unpleasant odors.

Control of the total sulfur content, hydrogen sulfide, and mercaptans ensures that the product is not corrosive or nauseating. Stipulating a satisfactory copper strip test further ensures the control of the corrosion.

Residue

The presence of any component substantially less volatile than the main constituents of the LPG will give rise to unsatisfactory performance. It is difficult to set limits to the amount and nature of the residue which will make a product unsatisfactory. Obviously, small amounts of oily material can block regulators and valves. In liquid vaporizer feed systems, even gasoline-type material could cause difficulty.

The residue as determined by the End Point Index (EPI) endeavors to give a measure of the higher-boiling hydrocarbon derivatives, but the relationship between EPI, hydrocarbon range, and performance is not established. Other methods are available which measure residue more directly, and for particular applications, it may be possible to relate the values obtained to the performance required and so set satisfactory limits.

Moisture and water

It is a fundamental requirement that any LPG should not contain free water. Dissolved water may give trouble by forming hydrates and giving moisture vapor in the gas phase. Both of these will lead to blockages. It is therefore necessary to limit the amount of dissolved water also.

Propanol

Propanol alcohol (propyl alcohol) is a three-carbon alcohol that has two isomers: (i) 1-propanol, *n*-propanol, or propan-1-ol: $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$, and (ii) 2-propanol, iso-propyl alcohol, isopropanol, or propan-2-ol: $(\text{CH}_3)_2\text{CHOH}$:

Both compounds are widely used as solvents and as intermediates in the production of various esters and amides. Isopropanol is also used as a disinfectant in pharmaceutical products or as an antifreeze. Currently, the main application of propanol today is for the synthesis of propylene which is an important building block in chemical industries. Propanol as a biofuel has received some attention in alcohol mixtures such as in isopropanol–butanol–ethanol fermentation.

See also: Propanol and Butanol.

Propanol and Butanol

Propanol (propyl alcohol) and butanol (butyl alcohol) exist in various isomeric (structural) forms – isomers are ions or molecules with identical formulas but distinct structures. Thus, for propanol and butanol, the isomers are *n*-propanol, isopropanol (or iso-propanol), *n*-butanol, iso-butanol (more often referred to as *sec*-butanol or secondary butanol), and tertiary-butanol. The various structures are as follows:

The unmodified term *butanol* usually refers to the straight chain isomer with the alcohol functional groups at the terminal carbon, which is also known as *n*-butanol or 1-butanol. The straight chain isomer with the alcohol at an internal carbon is *sec*-butanol or 2-butanol. The branched isomer with the alcohol at a terminal carbon is iso-butanol (isobutanol) or 2-methyl-1-propanol, and the branched isomer with the alcohol at the internal carbon is tert-butanol or 2-methyl-2-propanol. These two alcohols are considerably less toxic and less volatile than methanol. In particular,

butanol has a high flash point of 35°C (95°F), which is a benefit for fire safety, but may be a difficulty for starting engines in cold weather. Propanol and butanol are considerably less toxic and less volatile than methanol. In particular, butanol has a high flashpoint of 35°C, which is a benefit for fire safety, but may be a difficult for starting engines in cold weather.

Also, the different isomers forms can cause subtle-to-significant differences in the properties of the respective isomers. For example, the butanol isomers have different melting and boiling points. *n*-butanol and isobutanol have limited solubility in water (73 g/L at 25°C); *sec*-butanol has substantially greater solubility in water (290 g/L), while *tert*-butanol is miscible with water above the melting point of *tert*-butanol. The hydroxyl group makes the molecule polar, promoting solubility in water, while the longer hydrocarbon chain mitigates the polarity and reduces solubility.

The fermentation processes to produce propanol and butanol from cellulose are fairly tricky to execute, and the *Clostridium acetobutylicum* currently used to perform these conversions produces an extremely unpleasant smell, and this must be taken into consideration when designing and locating a fermentation plant. This organism also dies when the butanol content of whatever it is fermenting rises to 7%. For comparison, yeast dies when the ethanol content of its feedstock hits 14%. Specialized strains can tolerate even greater ethanol concentrations – the so-called turbo yeast can withstand up to 16% ethanol. However, if ordinary *Saccharomyces* yeast can be modified to improve its ethanol resistance, scientists may yet one day produce a strain of the Weizmann organism with a butanol resistance higher than the natural boundary of 7%. This would be useful because butanol has a higher energy density than ethanol, and because waste fiber left over from sugar crops used to make ethanol could be made into butanol, raising the alcohol yield of fuel crops without there being a need for more crops to be planted.

Proteins

Proteins are nitrogen-containing organic substances which occur in the protoplasm of all plant and animal cells. The composition of proteins varies with the source.

The characteristic structural feature of proteins is a chain (or ring) of amino acids joined together by amide linkages. Peptides are, in effect, a similar class of compounds, but the distinction between a protein and a peptide is not always clear. One arbitrary choice is to use a molecular weight of 10,000 as a distinction between the two classes with proteins having a molecular weight in excess of 10,000 while peptides have a molecular weight below this value.

The distinction might also be made in terms of differences in physical properties such as the degree of hydration and spatial arrangement of the molecules. For example, the naturally occurring peptides have relatively short, flexible chains and, although hydrated in aqueous solution, can be reversibly dehydrated. On the other hand, proteins have long chains which have definite conformational character with water molecules filling the interstices.

The special character of proteins derives not only from the length and complexity of the chains but also from the way in which they are synthesized by organisms in an often metastable form that can be easily and conveniently altered (denatured). The three-dimensional (spatial) character of proteins has an interesting arrangement that involves an alpha-helix.

The principal feature of this helix is the coiling of peptide chains in such a way as to form a hydrogen bond between the amide hydrogen and the carbonyl group at spatially convenient points in the chain. Such bonds are due to the polarization of various organic functional groups where adjacent hydrogen is positively polarized and a heteroatom (an atom other than carbon and hydrogen, usually oxygen) is negatively polarized. The strengths of these bonds are usually on the order of 5 to 10 kcal compared with 60 to 100 kcal for the conventional organic sigma-bonds. There is the potential for the formation of much more stable hydrogen bonds within the protein helix resulting in the formation of ring systems which tend to confer an additional stability (10 to 20 kcal) on the system.

The amino acid side chains lie outside the coil of the helix. Not all proteins are perfect alpha-helices since the steric effects between certain amino acid side chains may be sufficient to influence the stability of the helix.

Proteins occur throughout nature in a wide variety of sizes and shapes, and many proteins contain metals such as iron, zinc, and copper which, in turn, are intimately involved in the physiological (biological) functions of the molecules to which they are bound.

Protium

Hydrogen has three naturally occurring isotopes, sometimes denoted ¹H (sometimes referred to as protium, hydrogen-1), ²H (deuterium, hydrogen-2), and ³H (tritium, hydrogen-3) (Table P-14). The first two of these isotopes are stable, while tritium has a half-life of 12.32 years. The symbols D and T are sometimes used for deuterium and tritium, respectively.

Table P-14 The isotopes of hydrogen.

Isotope	Description
Protium	Ordinary hydrogen with one proton and one electron in the atom. When two atoms of protium are combined with one atom of oxygen, water is created.
Deuterium	Sometimes called “heavy hydrogen,” a non-radioactive isotope that has a neutron in the atom, in addition to the proton and electron. Water made with this isotope is called “heavy water.”
Tritium	A radioactive isotope of hydrogen that has two neutrons in addition to the proton and the electron. Water made with this isotope is called tritium oxide. Tritium is the only one of the three hydrogen isotopes that is radioactive.

The ¹H isotope is the most common hydrogen isotope with an abundance of more than 99.98%. The nucleus of this isotope consists of only a single proton which has never been observed to decay and is, therefore, considered to be a stable isotope. To date, experiments have shown that the minimum proton half-life is in excess of 10³⁴ years.
See also: Deuterium, Hydrogen, Tritium.

Proton

A proton is a subatomic particle (symbol p or p⁺), with a positive electric charge of +1e elementary charge and a mass slightly less than that of a neutron. Protons and neutrons, each with masses of approximately one atomic mass unit, are collectively referred to as nucleons (i.e., particles present in atomic nuclei).
One or more protons are present in the nucleus of every atom and are a necessary part of the nucleus. The number of protons in the nucleus is the defining property of an element, and is referred to as the atomic number (represented by the symbol Z), and, since each element has a unique number of protons, each element has its own unique atomic number.
See also: Electron, Periodic Table of the Elements.

Proven Reserves

Proven reserves (proved reserves) are those reserves of crude oil that are actually found by drilling operations and are recoverable by means of current technology (Table P-15). They have a high degree of accuracy and are frequently updated as the recovery operation proceeds.

Table P-15 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

The proven reserves may be updated by means of reservoir characteristics, such as production data, pressure transient analysis, and reservoir modeling.

Proven reserves are reserves considered to have a 90% probability of being recoverable. Unproven reserves are not deemed recoverable, due to regulatory or economic factors. This class of reserves is further broken down into (i) probable reserves and (ii) possible reserves. Probable reserves are reserves that have an estimated confidence level of approximately 50% of being successfully recovered, while possible reserves are those reserves with only a 10% probability of recovery.

If deterministic methods are used, the term reasonable certainty is intended to express a high degree of confidence that the quantities will be recovered. If probabilistic methods are used, there should be at least a 90% probability that the quantities actually recovered will equal or exceed the estimate.

Proximate Analysis

The proximate analysis test methods were originally developed as a part of the assay of coal but can be applied to many other carbonaceous materials. By definition, the proximate analysis separates the products into four groups which are (i) the moisture content, (ii) the volatile matter production which is often erroneously referred to as volatile matter content even though the unprocessed sample does not contain volatile matter, consisting of gases and vapors driven off during pyrolysis, (iii) the fixed carbon, the non-volatile fraction of the sample, and (iv) ash which is the inorganic residue remaining after combustion and is a reflection of the mineral matter content of the sample. On occasion, proximate analysis may also include ash fusion temperature.

A typical proximate analysis includes the moisture, ash, volatile matter, and fixed carbon contents. Fixed carbon is the material, other than ash, that does not vaporize when heated in the absence of air. It is usually determined by subtracting the sum of the first three values – moisture, ash, and volatile matter – in weight percent from 100%) and is important for economic reasons to know the moisture and ash contents of a coal because they do not contribute to the heating value of a coal. In most cases, ash becomes an undesirable residue and a source of pollution, but for some purposes (*e.g.*, use as a chemical feedstock or for liquefaction), the presence of mineral matter may be desirable. Most of the heat value of a coal comes from its volatile matter, excluding moisture, and fixed carbon content. For most coals, it is necessary to measure the actual amount of heat released upon combustion [expressed in British thermal units (BTUs) per pound or megajoules per kilogram].

The methods of analysis associated with the proximate analysis is, in fact, a combination of the determination of each of three of the properties and calculation of a fourth. Moisture, volatile matter, and ash are all determined by subjecting the sample to prescribed temperature levels for prescribed time intervals. The losses of weight are, by stipulation, due to loss of moisture and, at the higher temperature, loss of volatile matter. The residue remaining after ignition at the final temperature is called ash. Fixed carbon is the difference of these three values summed and subtracted from 100.

The term volatile matter content is actually a misnomer insofar as the majority of the volatile matter is the volatile product of the thermal decomposition of coal through the application of high temperatures. Relative yields and boiling point profiles provide the extent to which natural molecules contribute to the volatile matter without any influence from high-temperature cracking.

The final results of the proximate analysis are usually reported to the first decimal place. The final report of the analysis should always contain the results on a basis of air-dried coal (*i.e.*, coal in its most stable condition and in which it was analyzed), but for purposes of classification or comparison, it is often necessary to convert to another basis such as dry sample, dry-ash-free sample, or as received sample.

P-Series Fuels

A P-series fuel is a blend of natural gas liquids, ethanol, hydrocarbon derivatives, methyl tetrahydrofuran ($\text{CH}_3\text{C}_4\text{H}_7\text{O}$) and is a biomass-derived product. These fuels are clear, colorless liquid blends (octane number: 89-93) that are formulated to be used in flexible fuel vehicles. Like gasoline, low vapor pressure formulations are produced to prevent excessive evaporation during summer and high vapor pressure formulations are used for easy starting in the winter.

Also, these fuels are at least 60% non-crude oil constituents and the majority of the components that make up P-series fuels come from domestically produced renewable resources.

The P-Series fuels provide significant emissions benefits over reformulated gasoline. Each unit of P-series fuel emits approximately 50% less carbon dioxide, 35 % less hydrocarbon derivatives, and 15% less carbon monoxide than gasoline. The fuel also has 40% less ozone-forming potential. The other gasoline-substitute ether, MTBE (methanol tertiary butyl ether) is a crude oil-derived product and is made from isobutene [$(\text{CH}_3)_2\text{CH}=\text{CH}_2$ and methanol]. The P-series fuel emissions are generally below those for reformulated gasoline and are well below federal emissions standards. P-series fuels join the list of alternatives to gasoline that includes ethanol (E85), methanol (M85), natural gas, propane, and electricity.

See also: Fuels.

Pullman-Kellogg Process

The Pullman-Kellogg molten salt process is a process that was developed for the gasification of coal but which has the potential to be adaptable to other carbonaceous feedstocks. In the process, air is bubbled into the bottom of the gasifier through multiple inlet nozzles and the feedstock (sized to 1/4 in.; 6 mm) is fed beneath the surface of the molten salt bath using a central coal feed tube whereupon natural circulation and agitation of the melt disperses the coal.

The main gasification reaction is a partial oxidation reaction, and volatile matter in the feedstock reacts to produce a fuel gas free of oils, tars, as well as ammonia. A water-gas shift equilibrium exists above the melt, and, accordingly, in the reducing environment, carbon dioxide and water concentrations are minimal. Sulfur in the coal reacts with the melt to form sodium sulfide.

See also: Biomass Gasification, Gasifiers.

Pulping

Like delignification, pulping is another method by which wood is prepared for use in other areas but which also has potential in preparing wood for conversion to fuels and other chemicals.

In a chemical pulping process, heat and chemicals are added to wood chips in a pressure cooker called the digester. In the kraft process, an aqueous solution of sodium hydroxide and sodium sulfide, known as white liquor, selectively dissolves the lignin and make it soluble in the cooking liquid. After 2 to 4 hours, the mixture of pulp, spent pulping chemicals, and wood waste is discharged from the digester. The pulp is washed to separate it from the black liquor – the pulping chemicals and wood waste. Kraft pulping is a low yield process – approximately 45% w/w of the wood used becomes pulp. The pulp, called brown stock at this point in the process, is ready to be bleached. Softwood pulp from a conventional cooking process contains approximately 4.5% lignin. This lignin will be removed, and the pulp will be brightened during the bleaching process.

Efficient pulp washing is important because it ensures the maximum recovery of the pulping chemicals and it minimizes the amount of organic waste carried over with the pulp into the bleaching process. Poorly washed pulps require higher bleaching chemical doses, thus increasing the cost and the amount of organic waste discharged in the bleach plant effluent.

The chemical recovery process has four steps which are (i) the water from the washer goes to the evaporator, where the black liquor is concentrated to 65% to 75% solids prior to its entry to the recovery boiler, (ii) in the recovery boiler, a specially-designed furnace, the used pulping chemicals are separated from the wood waste – the pulping chemicals form a lava-like smelt at the base of the recovery boiler; the wood waste is burned at the top of the recovery boiler, and this heat is used to generate high-pressure steam, which can be used to meet the steam and electricity requirements of the process, (iii) the smelt is poured into a large tank of water to form green liquor, a mixture of sodium sulfide and sodium carbonate, and (iv) lime addition, which involves the addition of calcium oxide to the green liquor to convert the sodium carbonate into sodium hydroxide, and thus remake the white liquor; the resulting calcium carbonate is converted back to lime in a lime kiln.

Conventional pulping processes remove approximately 95% w/w of the lignin from the pulp. In the past, the remaining lignin was removed during the bleaching process. Oxygen has been used to remove lignin from pulp on

a mill scale since the late 1970s. Scandinavian mills first installed oxygen delignification in response to concerns related to the amount of organic waste in the effluent. Union

The pulp is washed after it leaves the tower where it has reacted with oxygen. The wastewater or filtrate can either be used in the brown stock washers, or it can be routed directly to the evaporator where it will be combined with the black liquor. The degraded lignin products will be burned for energy in the recovery boiler, so less organic waste will be discharged in the waste water from the bleach plant.

Digesters can be modified to remove more lignin from the pulp without damaging the cellulose by using the same amount of white liquor, but adding it at several points during the cooking process. This additional wood waste is also sent to the recovery system.

Extended delignification and oxygen delignification are proven technologies that can remove as much as 70% of the lignin before the bleaching process removes the remaining lignin and colored substances. To produce high-quality totally chlorine-free pulp (TCF), mills will have to install oxygen delignification, extended delignification, or both in order to minimize the use of chemicals in the bleach plant. More organic waste is burned in the recovery boiler, and smaller quantities of bleaching chemicals are required.

Pulpwood

Pulpwood is round wood, whole-tree chips, or wood residues that are used for the production of wood pulp. The composition of pulpwood varies with the source trees (Table P-16).

Table P-16 Examples of the chemical constituents of pulpwood.

Wood	Cellulose	Lignin	Xylan	Other
Aspen	56.5	16.3	16.0	11.2
Balsam fir	47.4	29.4	4.8	15.4
Birch	44.5	18.9	24.6	12.0
Jack Pine	45.0	28.6	7.1	19.3
Maple	44.8	24.0	17.3	13.9
White spruce	48.5	27.1	6.8	17.6

Pulpwood is also used as the raw material for some wood products, such as oriented strand board (OSB), and there is an increasing demand for pulpwood as a source of bio-energy. Trees raised specifically for pulp production account for 16% of world pulp production, old growth forests 9% and second- and third- and more generation forests account for the balance. Reforestation is practiced in most areas, so trees are a renewable resource.

In the logging of mixed forest stands, the better trees are usually used for sawlogs for lumber production, while the inferior trees and components are harvested for pulpwood production. Pulpwood usually derives from four types of woody materials in a mixed logging operation: (i) open-grown trees, that are heavily branched low on the trunk, and so make poor sawlogs, (ii) dead or diseased trees, (iii) tops cut from trees harvested for sawlogs (branches are rarely used since they contain little usable wood after the bark has been removed), and (iv) trees too small to harvest for sawlogs.

Pulpwood is also harvested from plantations/tree farms established for the specific purpose of growing pulpwood, with little or minimal sawlog production. Monocultures of species intended specifically for pulpwood include loblolly/slash pine in the southern USA; various species of eucalyptus (most commonly *Eucalyptus globulus* and *Eucalyptus grandis*) in Latin America, the Iberian Peninsula, Australia, south-east Asia, and southern Africa and acacia (most commonly *Acacia mangium*) in south-east Asia and southern Africa.

Natural forest stands may also be harvested solely for pulpwood where, for various reasons, the value of the trees as sawlogs is low. This may be due to the predominant species in the forest stand (for example, some aspen forests in northern North America), or to the relative proximity of the nearest sawmill or pulp mill.

Pulpwood trees are any commercial tree species that does not have the size or quality to make other wood products. This includes large trees with defects or multiple branches eliminating sawtimber possibilities and trees too

small to be cut for sawtimber. Pulpwood trees have to be at least 5 inches diameter at breast height (dbh) and do not bring as much money to the as sawtimber size trees.

Salvage cuts after forest fires, tornadoes, hurricanes, or other natural disasters are often also for pulpwood. An alternative source of wood for use in kraft pulping is recovered lumber from demolition, industrial processing of wood, and wooden pallets.

See also: Logs and Woodchips, Wood.

Puraspec Process

The Puraspec processes use fixed beds of catalysts and chemical absorbents to remove traces of contaminants from hydrocarbon gases and liquids. In particular, the processes are designed to remove mercury and a range of sulfur compounds – most frequently hydrogen sulfide (H_2S) and carbonyl sulfide (COS). Mercury removal from hydrocarbon streams is a stringent requirement in order to avoid corrosion of equipment, poisoning of catalysts, and to comply with environmental regulations.

The processes are used for *sweetening* to meet pipeline specifications and *polishing* to meet individual feedstock requirements. The fixed beds of chemical absorbents provide effectively total irreversible selective removal of impurities from wet or dry hydrocarbon derivatives without feedstock losses.

See also: Gas Cleaning, Gas Processing.

Purisol Process

The Purisol process is designed for the selective desulfurization of raw gas streams (including natural gas) from various processes.

In the process, N-Methyl-2-Pyrrolidone (NMP) is used as physical solvent. The solvent absorbs the undesired components carbon disulfides, hydrogen sulfide, carbonyl sulfide, hydrogen cyanide, and ammonia as well as carbon dioxide. These components are subsequently desorbed by reducing the pressure and reboiling the solvent.

As the solubility of hydrogen sulfide is significantly higher than that of carbon dioxide, little carbon dioxide is co-absorbed. Consequently, Claus gas with particularly high concentrations of hydrogen sulfide can be produced. Hydrogen cyanide and higher- molecular-weight sulfur compounds are also discharged into the Claus gas. The solubility increases steeply as the temperature decreases. For this reason, absorption is performed at low temperatures, while high temperatures are used for regeneration.

Where required, impurities such as hydrogen cyanide or higher-molecular-weight sulfur compounds are removed from the cooled raw gas in a prewash stage of the absorber. In the main absorber section, the sulfur compounds, in particular hydrogen sulfide, are removed from the raw gas until reaching the admissible residual concentration.

The solvent from the hot regeneration, which has been subsequently cooled, is added at a temperature ranging between ambient temperature and $-10^{\circ}C$. Before the desulfurized clean fuel gas leaves the absorber, traces of NMP can be removed in a water wash.

The solvent from the hydrogen sulfide absorber contains large quantities of hydrogen sulfide and little carbon dioxide. It is relieved to a lower pressure in the bottom section of the reabsorber, whereby carbon dioxide and small quantities of hydrogen sulfide are desorbed. The solvent from the hot regeneration in the upper section of the reabsorber immediately reabsorbs the hydrogen sulfide. As a consequence, sulfur-free gas leaves the reabsorber, which can either be rerouted to the raw gas stream or used as fuel gas.

The solvent from the reabsorber is heated and further flashed in the hot flashing stage. Any carbon dioxide removed in this stage is returned to the reabsorber. The solvent leaving the hot flashing stage is completely regenerated by reboiling in the lower part of the hot regeneration. The hydrogen sulfide-rich gas is then routed to the downstream Claus unit. An adequate adjustment of pressures and temperatures allows for extremely high concentrations of hydrogen sulfide.

The gas rich in hydrogen sulfide is processed in a Claus plant and a hydrogenation unit, yielding pure sulfur from hydrogen sulfide. The sulfur compounds produced in the Claus process are converted to hydrogen sulfide by adding

hydrogen in the hydrogenating unit. The exhaust gas from hydrogenation is cooled to condense the water contained in the gas. The gas is then returned to the reabsorber to be completely desulfurized.

Since the process reduces the sulfur content in the fuel gas to only a few ppm hydrogen sulfide, high desulfurization efficiency can be achieved. If the raw gas contains material quantities of carbonyl sulfide, they have to be treated by catalytic hydrolyzation before the hydrogen sulfide wash.

Purox Process

The Union Carbide PUROX process employs a partial oxidation process using oxygen for converting municipal solid waste to fuel gas and inert slag.

This conversion is accomplished by (i) shredding and preparing the refuse for conversion, (ii) producing a gas of low calorific value from the refuse, and (iii) methanation of the off-gas to a quality suitable for sale in the existing gas distribution system.

The principal component of the Purox system is a vertical shaft reactor. Solid waste, either raw or processed, is introduced into the top of the furnace and via an airlock feeder. Simultaneously, pure oxygen is forced into the base of the column at the rate of approximately 0.2 Mg per Mg of solid waste. Char formed from the solid waste reacts with the incoming oxygen, generating temperatures on the order of 1,370 to 1,660°C (2,500 to 3,020°F). Gases formed in the reaction between the oxygen and the char ascend to the top of the retort, countercurrently to the incoming waste. In the process, the combustion of the gases supplies the energy required to drive the pyrolysis reaction. As the gases approach the top of the retort, they dry the incoming waste and, consequently, are further cooled to approximately 90°C (195°F). The off gas contains certain impurities that are removed in a gas cleaning system, which consists of an electrostatic precipitator, an acid absorption column, and a condenser.

Low-Btu off-gas, with a heating value of 590 Btu/ft³, to synthetic natural gas (SNG), which is comprised mostly of methane and which has a heating value of 879 Btu/ft³. Upgrading is accomplished by a series of clean-up and catalytic conversion steps.

The clean-up steps encompass a benzol wash for removal of residual hydrocarbon liquids from the off-gas, sulfur and chloride removal, carbon dioxide removal, and dehydration. The catalytic conversion steps consist of hydrogenation and methanation.

Approximately one ton of refuse requires approximately 0.2 ton of oxygen and produces 0.7 ton of medium Btu fuel gas, 0.22 ton of sterile residue, and 0.28 ton of wastewater. Refuse, preprocessed for recovery of iron and other materials, is fed to the top of a vertical shaft furnace through a gas seal, and oxygen is injected into the bottom hearth section. The reaction of oxygen with char formed from the particles of refuse generates high temperatures which melt glass, metal, and other materials. Hot gases from this process are used to pyrolyze the refuse, and the resulting fuel gas is cleaned. A gas analysis and slag analysis are provided, and several features of the system are discussed.

Pyridine Bases

Pyridine is a basic heterocyclic organic compound with the chemical formula C₅H₅N. It is structurally related to benzene, with one methine group replaced by a nitrogen atom.

Pyridine is a highly flammable, weakly alkaline, water-miscible liquid with a distinctive, unpleasant fish-like smell.

The nitrogen center of the pyridine molecule features a basic lone pair of electrons which does not overlap with the aromatic π -system ring; consequently pyridine is basic, having chemical properties similar to those of tertiary amines.

In addition to ammonia, a gas stream may contain small quantities of miscellaneous compounds which may be removed for their own value or to improve the gas product; among the more common of these are pyridine bases and hydrogen cyanide. The former are nitrogen-containing organic materials which belong to the pyridine series (C_5H_5N) and which occur in coal tar. They can be removed from the gas by reaction with sulfuric acid, which converts the bases to nonvolatile sulfate derivatives, and the pyridine derivatives can be recovered as a valuable by-product from the scrubber liquor by neutralizing the liquor with ammonia followed by steam distillation of the uncharged bases. The condensate is saturated with ammonium sulfate, which reduces the solubility of the uncharged bases and causes them to precipitate from solution.

Pyrolysis

Pyrolysis (also called devolatilization) is the process of the thermal decomposition of biomass at high temperatures (greater than 205°C, 400°F) in the absence of air; the end product of pyrolysis is a mixture of solids (char), liquids (oxygenated oils), and gases (methane, carbon monoxide, and carbon dioxide) with proportions determined by operating temperature, pressure, oxygen content, and other conditions (Table P-17)

Table P-17 Products of pyrolysis and potential uses.

Feedstock	Primary product	Secondary product
Biomass, waste	Gases	Fuel gas
		Synthesis gas
	Bio-oil	Fuel oil
		Convert to gasoline
		Convert to diesel fuel
	Char	Solid fuel
		Activated carbon
		Filler

When carbonaceous materials, such as biomass, are pyrolyzed, hydrogen-rich volatile matter is distilled and a carbon-rich solid residue is left behind. The carbon and mineral matter remaining behind is the residual char. In this regard, the term carbonization is sometimes used as a synonym for coal pyrolysis.

However, carbonization has as its aim the production of a solid char, whereas in synthetic fuel production, the greatest interest centers on liquid and gaseous hydrocarbon derivatives.

Pyrolysis is one method to produce liquid fuels from biomass. Moreover, as gasification and liquefaction are carried out at elevated temperatures, pyrolysis may be considered a first stage in any conversion process. The study of pyrolysis can be dated from the end of the eighth century when Arabian scientists produced liquids from bitumen. Despite the many advances in understanding achieved since that time, there is still not a unified fundamental picture of the complex chemical and physical phenomena that take place, which given the raw material and the physical conditions of heating, would enable a unique determination of the products.

Of most interest in the production of synthetic fuels from biomass is the prediction of the rate and amount of volatile yield and product distribution for a given raw material and the set of pyrolysis conditions. Among the important chemical variables are the elemental composition and chemical composition. Above 100°C and below 300°C, the evolution of volatile matter is not large and the volatile material is composed of oxides of carbon and water. In the active or second stage of decomposition, approximately 75% of all the volatile matter ultimately released is evolved. In the third stage, there is a secondary degasification associated with the transformation of the char, accompanied by the release of non-condensable gases, mainly hydrogen.

In all stages of pyrolysis, but particularly the higher temperature ones, it is important to distinguish between the primary volatile products of decomposition and those products which result from secondary cracking and coking reactions and from gasification reactions such as between the char and evolved water.

The effect of heating rate on the amount and composition of pyrolysis volatile yields has been an important issue.

The relative quantity of char, tars, and gases evolved on pyrolysis is strongly dependent both on the rate of heating and the final temperature attained. Slow-heating, low temperature pyrolysis favors char yields. In theory, cellulose can be carbonized to yield carbon and water only. In practice, the initial decomposition product of cellulose pyrolysis is levoglucosan, $C_6H_{10}O_5$, an anhydride of glucose. Subsequent coking and cracking reactions result in a char that contains oxygen and hydrogen in addition to the carbon. The char remaining on pyrolysis of wood contains approximately 80% carbon, 17% oxygen, and 3% hydrogen.

Particle size is known to influence pyrolysis yield. This effect may be related to heating rate, in that larger particles will heat up more slowly, so the average particle temperatures will be lower, and hence volatile yields may be expected to be less. If the particle size is sufficiently small, it will be heated uniformly. When finely ground carbonaceous particles are heated rapidly, larger yields than the functional composition of the organic and inorganic matter, as well as the composition of the ambient gas in which the pyrolysis takes place. Among the more important basic physical variables are the final temperature, the time and rate of heating, the particle size distribution, the type and duration of any quenching, and the pressure. An indication of the uncertainty existing in this field is that at present, there is no agreement on whether yield, which is the loss in mass of the raw material from pyrolysis, is changed with heating rate.

The composition of the volatile products evolved in pyrolysis is largely determined by the raw organic material. In the case of biomass, at 500°C, the major constituents of the gas include carbon oxides, methane, hydrogen, and low molecular weight along with hydrogen sulfide and ammonia.

Pressure may be expected to affect volatile yields, with higher pressures reducing the yields and lower ones increasing them. However, higher pressures favor cracking reactions, so high pressure will produce a larger volume of low-boiling hydrocarbon derivative (gases), whereas lower pressure will lead to higher yields of high-boiling (often viscous) oil fractions and tar.

Pyrolysis in a hydrogen atmosphere, termed *hydropyrolysis*, can increase the volatile yield and proportion of lower-molar-mass hydrocarbon derivatives. Hydropyrolysis is defined to include thermal decomposition and the attendant hydrogenation but not the hydrogasification of the char. Hydrogen reacts much faster with decomposing organic material and with the primary volatiles than with residual char. The increase in volatile yield is attributable to the hydrogenation of free radical fragments sufficient to stabilize them before they react and form char.

Rapid pyrolysis (fast pyrolysis) involves the collection of the volatile matter and depending on the temperature of the process these materials can be combusted. This liquid product has the potential to be used as fuel oil. Temperatures range from 800 to 900°C. Fast pyrolysis can leave as little as 10% char and can convert as much as 60% into a gas.

Pyrolysis – Biomass

Pyrolysis of biomass at high temperatures (greater than 205°C, 400°F) in the absence of air results in a mixture of (i) gases, such as methane, carbon monoxide, and carbon dioxide, (ii) liquids, such as oxygenated oils, and (iii) solids, often referred to as char), with proportions determined by operating temperature, pressure, oxygen content, and other conditions.

When carbonaceous materials, such as biomass, are pyrolyzed, hydrogen-rich volatile matter is distilled and a carbon-rich solid residue is left behind. The carbon and mineral matter remaining behind is the residual char. In this regard, the term carbonization is sometimes used as a synonym for coal pyrolysis. However, carbonization has as its aim the production of a solid char, whereas in synthetic fuel production, the greatest interest centers on liquid and gaseous hydrocarbon derivatives. Thus:

Feedstock	Primary product	Secondary product
Biomass, waste	Gases	Fuel gas
		Hydrocarbon gases
		Synthesis gas
	Bio-oil	Fuel oil
		Convert to gasoline
		Convert to diesel fuel
	Char	Solid fuel
		Activated carbon
		Filler

Pyrolysis is one method to produce liquid fuels from biomass. Moreover, as gasification and liquefaction are carried out at elevated temperatures, pyrolysis may be considered a first stage in any conversion process.

The study of pyrolysis can be dated from the end of the eighth century when Arabian scientists produced liquids from bitumen. Despite the many advances in understanding achieved since that time, there is still not a unified fundamental picture of the complex chemical and physical phenomena that take place, which given the raw material and the physical conditions of heating would enable a unique determination of the products.

Of most interest in the production of synthetic fuels from biomass is the prediction of the rate and amount of volatile yield and product distribution for a given raw material and the set of pyrolysis conditions. Among the important chemical variables are the elemental composition and chemical composition. Above 100°C and below 300°C, the evolution of volatile matter is not large and the volatile material is composed of oxides of carbon and water. In the active or second stage of decomposition, approximately 75% of all the volatile matter ultimately released is evolved. Pyrolysis Processes

In a pyrolysis process, solid biomass (mainly herbaceous) is transformed into a liquid-state semi-finished material – pyrolysis slurry that is fed into the gasifier. Unlike gasification, pyrolysis represents thermal degradation of feedstock in the absence of an externally supplied oxidizing agent. As a result, pyrolysis yields mainly liquids (up to 80% on mass basis via gas condensing) and some tars and chars, while gasification output consists predominantly of gaseous products. For synthesis gas (and biomass-to-liquids) production, flash pyrolysis is typically employed.

Generally, pyrolysis is a medium temperature method which produces gas, oil, and char from crops which can then be further processed into useful fuels or feedstock. Pyrolysis is often considered to be the gasification of biomass in the absence of oxygen, but the chemistry of each process may differ significantly. In general, biomass does not gasify as easily as coal, and it produces other hydrocarbon compounds in the gas mixture exiting the gasifier; this is especially true when no oxygen is used. The products of biomass pyrolysis include gases such as methane, hydrogen, carbon monoxide, carbon dioxide, bio-oil, and char. As a result, typically an extra step must be taken to reform these products with a catalyst to yield a clean synthesis gas mixture of hydrogen, carbon monoxide, and carbon dioxide. Thus, when organic matter is heated at increasing temperatures in open containers, a variety of processes generally occur, in successive or overlapping stages.

Depending upon the operating conditions (temperature, heating rate, particle size and solid residence time), pyrolysis can be divided into three subclasses: conventional, thermal, or catalytic. For example, to maximize bio-oil production, fast/flash pyrolysis is used, heating the biomass to approximately 500°C (930°F) for less than ten seconds. In the pyrolysis of plastics, the macromolecular structures are broken down into smaller molecules (oligomers and monomers); further degradation depends on temperature, residence time, presence of catalysts, and other process conditions. Pyrolysis aims to convert waste into other valuable chemicals, which can be used as feedstock for downstream industrial processes or transportation fuels. The approaches: molten salts, cracking (catalytic, hydrocracking, and thermal), and liquefaction are discussed.

Molten salts such as lithium chloride-potassium chloride with 10% w/w cuprous chloride (LiCl-KCl-10% CuCl) at 520°C (970°F) are used to pyrolyze polymeric waste to yield a fuel oil. At a process temperature of 420°C (790°F), the gaseous fraction is minimized; this enables a higher liquid and solid fraction to be recovered. The recovered fractions consist of low-boiling oils, aromatic derivatives, paraffin waxes, and monomers.

In general, pyrolysis of organic substances produces volatile products and leaves a solid residue enriched in carbon (char) – as an example, pyrolysis is one of the processes involved in the reduction of char from wood. As another example, the process is used frequently in the chemical industry, for example, to produce ethylene, many forms of carbon, and other chemicals from crude oil, coal, and wood, to produce coke from coal. In the current context, other applications of pyrolysis would convert biomass into synthesis gas, waste plastics into usable oil, and char.

Fast pyrolysis is a thermal decomposition process that occurs at moderate temperatures with a high heat transfer rate to the biomass particles and a short hot vapor residence time in the reaction zone. Several reactor configurations have been shown to assure this condition and to achieve yields of liquid product as high as 75% based on the

starting dry biomass weight. They include bubbling fluid beds, circulating and transported beds, cyclonic reactors, and ablative reactors.

Briefly, ablative pyrolysis is conceptually different compared to other fast pyrolysis methods. Most pyrolysis processes depend on having a high heat-transfer rate, which determines the rate of the reaction, and, therefore, these systems employ small biomass particles. Ablative pyrolysis depends on heat transfer from the hot reactor wall to melt the wood particles contacting the wall under pressure. Unlike other pyrolysis processes, because the reaction rates are not limited by heat transfer through the biomass particle, large biomass particles up to lumber size may also be processed by an ablative pyrolysis reactor.

Fast pyrolysis of biomass produces a liquid product (referred to as pyrolysis oil or bio-oil) that can be readily stored and transported. Pyrolysis oil is a renewable liquid fuel and can also be used for production of chemicals. Fast pyrolysis has now achieved a commercial success for production of chemicals and is being actively developed for producing liquid fuels. Pyrolysis oil has been successfully tested in engines, turbines, and boilers, and been upgraded to high-quality hydrocarbon fuels. In the 1990s, several fast pyrolysis technologies reached near-commercial status and the yields and properties of the generated liquid product depend on the feedstock, the process type and conditions, and the product collection efficiency.

The direct hydrothermal liquefaction process involves converting biomass to an oily liquid by contacting the biomass with water at elevated temperatures (300 to 350°C, 570 to 660°F) with sufficient pressure to maintain the water primarily in the liquid phase residence times up to 30 minutes. Alkali may be added to promote organic conversion. The primary product is an organic liquid with reduced oxygen content (approximately 10%), and the primary by-product is water containing soluble organic compounds.

The importance of the provisions for the supply of feedstocks as crops and other biomass is often underestimated since it is assumed that the supplies are inexhaustible. While this may be true over the long term, the short-term supply of feedstocks can be as much as risky as any venture.

Hydrocracking of polymer waste involves reaction with hydrogen over a catalyst in a stirred batch autoclave at moderate temperatures and pressures. Typical plastic waste feedstock like polyethylene (PE), polyethylene terephthalate (PET), polystyrene, polyvinyl chloride (PVC), and mixed polymers are reacted in the presence of a catalyst (platinum, nickel, molybdenum, and iron on acid solids such as alumina, zeolites, and sulfonated zirconia) at 150 to 400°C (300 to 750°F) and hydrogen at 3 to 10 MPa to produce a high-quality gasoline.

Catalytic cracking involves a suitable catalyst to carry out the cracking reaction. The presence of catalyst lowers the reaction temperature and time. Catalytic degradation yields a narrow product distribution with a peak at lower-molecular-weight hydrocarbon derivatives and occurs at lower temperatures. Using solid acid catalysts, HZSM-5, HY, rare earth metal-exchanged Y-type (REY) zeolite, and silica-alumina for polymeric waste yields 30% w/w gasoline and 20% w/w high-boiling oil. The differences among catalysts arise in the production of coke and gas fractions. Formation of coke is not desirable as it results in catalytic deactivation by fouling and plugging the pore paths. Catalytic cracking, owing to its lower operating temperature, appears to be more technologically sound than thermal pyrolysis; however, it is more costly. The addition of a catalyst enhances the conversion and fuel quality, as compared to pure thermal pyrolysis.

There are numerous proposed mechanisms for catalytic degradation. These include the carbonium ion mechanism and the free radical mechanism. In the carbonium ion (R^+) mechanism, there are four steps: initiation, depropagation, isomerization, and aromatization. In the initiation step, the carbonium ion is generated through proton addition to an olefinic linkage, beta-scission, or through the abstraction of a hydride ion by low-molecular-weight carbonium ions.

In the depropagation step, the molecular weight of the main polymer chain can be successively reduced through beta-scission. In the isomerization step, the carbonium ion intermediates can undergo a hydrogen atom shift or a carbon atom shift, leading to rearrangement of the molecules. Some of the carbonium ion intermediates can also undergo cyclization reactions, which leads to the formation of aromatics (aromatization step).

In the free radical mechanism, there are the three known radical mechanism steps: initiation, propagation, and termination. Normally, random bond breaking generates a radical in the initiation step after which the radical is propagated via a number of reactions such as beta-scission, radical abstraction, and radical decomposition. Finally, recombination of two radicals leads to the termination step. The sequence can be represented more fully as:

Initiation:

Propagation:

Termination:

Thermal cracking (pyrolysis) involves the degradation of polymeric materials by heating in the absence of oxygen and is usually conducted between 350 and 900°C (650 to 1,650°F). The products formed are a carbonized char and a volatile fraction that may be separated into a condensable hydrocarbon oil consisting of paraffins, iso-paraffins, olefins, naphthenes, aromatics, and a non-condensable high calorific value gas.

The thermal pyrolysis of polymeric waste at temperatures higher than 480°C (895°F) yields a gas-liquid hydrocarbon. At 650 to 760°C (1,200 to 1,400°F), more of the gaseous product is generated; conversely, at lower temperatures, up to 85% of the product is liquid hydrocarbon derivatives. The portion of each fraction and their precise composition depends primarily on the properties of the waste plastic material(s) and the process parameters (temperature, pressure, residence time of the feedstock in the thermal zone). Both the gaseous and the liquid forms of the polymeric waste can be utilized as a feedstock to petrochemical facilities. Generally, thermal cracking results in liquids with low octane value and high residue content at moderate temperatures; this is an inefficient process for producing gasoline ranges. The gaseous products obtained by thermal pyrolysis are not suitable for use as fuel products and require further refining to be upgraded to usable fuel products. A few researchers have sought to improve thermal pyrolysis of waste plastics without employing the use of catalysts. However, these changes either yielded insignificant improvements or added another level of complexity and costs to the system.

Typically, discarded tires can be reduced in size by grinding, chipping, pelletizing, and passed through a classifier to remove the steel belting after which the chips are pyrolyzed for 1 hr at a temperature of 300 to 500°C (570 to 930°F) and then heated for 2 hr in a closed retort. The products are then distilled (purification and analysis) which yields oil and gas and char. However, discarded tires can also be debanded, shredded to 25 mm, and ground to 24 mesh as a feed preparation step for occidental flash pyrolysis which involves flash pyrolysis and product collection. The pyrolytic reaction occurs without the introduction of hydrogen or using a catalyst. This yields a gaseous stream that is passed to a quench tower from which fuel oil and gas (recycled to char fluidized and pyrolysis reactor as a supplemental fuel) and carbon black (35% w/w) is produced.

Hydrothermal liquefaction and pyrolysis are often confused since both are thermochemical processes where organic compounds are converted to liquid products. However, in hydrothermal liquefaction, macro-molecules are decomposed into unstable, reactive low-molecular-weight products in the presence of a catalyst. These fragments repolymerize into high-molecular-weight oily compounds.

The hydrothermal liquefaction process involves solvolysis, decarboxylation, hydrogenolysis, and hydrogenation, leading to challenging mechanistic transformation studies. During solvolysis, the solvent reacts with the molecule, helping to begin the degradation of the biomass. Depolymerization of hemicelluloses, cellulose, and lignin further degrades the biomass to smaller molecules. In decarboxylation, loss of carbon dioxide can lead to rearrangement of

the molecule. Molecules can also be further transformed via hydrogenolysis (water molecules split into a hydrogen ion, H^+ , and a hydroxyl ion, OH^- , and react with feedstock molecules) and hydrogenation (hydrogen is added to the molecule).

Similar to entrained flow gasification, in flash pyrolysis, the residence time of fuel is short – on the order of several seconds. Unlike entrained flow gasification however, the optimum process temperature is much lower – [approximately $500^{\circ}C$ ($930^{\circ}F$)] and the operating pressure is nearly atmospheric – approximately 14.7 psi. The chopped biomass (particles of less than 5 mm) is not heated directly, but with a hot sand medium (similar to fluidized bed gasification) in proportion 1:20, respectively. The pyrolysis gases are cooled down as quickly as possible (in a few seconds) to temperatures below $100^{\circ}C$ ($212^{\circ}F$), and a liquid condensate (pyrolysis oil) is obtained.

The char from pyrolysis is separated from the sand in a cyclone and then milled. The char powder is mixed with the pyrolysis oil, forming a pyrolysis-char slurry, which increases the overall carbon conversion efficiency. The sand separation from the char does not have to be 100% effective since some material of similar type should anyhow be added to the entrained flow gasifier to improve molten slag properties.

Pyrolysis is particularly suitable for herbaceous biomass also because the alternative pre-treatment – fine shredding – is much more difficult and costly compared to that of wood. The pyrolysis slurry feeding into the gasifier with sufficient extent of atomization to ensure full and complete gasification is, however, still a major technical challenge.

Pyrolysis oil is a strong acid which means it is a powerful corrosive substance. Its handling, storage, and transportation therefore require sophisticated and expensive materials, i.e., stainless steel tanks. In addition, there are some concerns related to the potential carcinogenic impact of pyrolysis slurry. The relatively low flash point of pyrolysis oil also imposes additional safety requirements for handling, storage, and transportation.

Pyrolysis Oil

Pyrolysis oil (often referred to as bio-oil and sometimes called bio-crude) is the liquid condensate produced from biomass (forestry residues, crop residues, waste paper and organic waste) by means of processes such as pyrolysis and thermochemical conversion. Depending on the composition of the feedstock and the process, the yield of bio-oil from wood, paper, and other biomass ranges on the order of 60 to 95% w/w wt%. The yield of bio-oil from wood can range from 72 to 80% w/w, depending on the relative amounts of cellulose and lignin in the material. Materials with a high lignin content, such as bark, tend to give lower liquid yields (typically, 60 to 65% w/w), but these are offset somewhat by a higher energy density in the liquid. Materials such as paper, which are high in cellulose content, give bio-oil yields in the range of 75 to 93% – yields in excess of 75 wt% are typical of a mixed paper stream.

The pyrolysis process results in the transformation of a solid or moist feedstock into a liquid, with conversion efficiency normally exceeding 50%. Considerable quantities of char and other waste products are also produced and must be disposed of. The chemical composition of pyrolysis oil is highly dependent upon the feedstock utilized, but the process itself inevitably results in a complex mixture of chemicals, primarily consisting of hydrocarbon derivatives, and sometimes totaling more than a hundred. Pyrolysis oil is characteristically fairly viscous, brown in color, unstable, and quite corrosive. Energy content varies, but is roughly on a par with that of the viscous high-boiling residual crude oil used for heating and for fueling large ships.

Bio-oil is typically a liquid, almost black through dark red-brown. The density of the liquid is approximately $1,200\text{ kg/m}^3$, which is higher than of fuel oil, and significantly higher than of the original biomass. The viscosity of the oil varies from as low as 25 cP up to 1,000 cP depending on the water content, and the original feedstock. Due to large amounts of oxygenated components present, bio-oil has a polar nature and does not mix readily with hydrocarbon derivatives. The degradation products from the biomass constituents include organic acids (like formic and acetic acid), giving the oil its low pH of approximately 2 to almost 4. Typically, bio-oil is a low-sulfur, non-viscous, renewable liquid fuel – it is an oxygenated and, as such, is not a hydrocarbon fossil fuel. The oil has a fuel value of least 7,500 BTU/lb, which is approximately the same as air-dried wood and is between the fuel value of methanol and crude oil-derived fuel oil. Bio-oil is a clean-burning fuel that can be fired in existing fossil fuel boilers with minimal modifications, although the tendency for any signs of incompatibility with crude oil-derived fuel oils should be investigated before blending.

Water is an integral part of the single-phase chemical solution. The (hydrophilic) bio-oils have water contents of typically 15-35 wt.%. Typically, phase separation does occur if the water content is higher than approximately 30 to 45%. The heating values: the higher heating value (HHV) is below 19 MJ/kg compared to 42-44 MJ/kg for conventional fuel oils.

A totally different process than that used for biodiesel production can be used to convert biomass into a type of fuel similar to diesel which is known as bio-oil. The process (*fast pyrolysis, flash pyrolysis*) occurs when solid fuels are heated at temperatures between 350 and 500°C (660 to 930°F) for a short period of time (<2 seconds). The bio-oils currently produced are suitable for use in boilers for electricity generation.

In another process, the feedstock is fed into a fluidized bed (at 450 to 500°C, 840 to 930°F) and the feedstock flashes and vaporizes. The resulting vapors pass into a cyclone where solid particles, char, are extracted. The gas from the cyclone enters a quench tower where it is quickly cooled by heat transfer using bio-oil already made in the process. The bio-oil condenses into a product receiver, and any non-condensable gases are returned to the reactor to maintain process heating. The entire reaction from injection to quenching takes only two seconds.

In the hydrothermal upgrading process (HTU process), biomass is treated with water at high temperature (300 to 350°C, 570 to 660°F) and pressure (1,770 to 2,650 psi) to produce bio-crude. This can be separated by flashing or extraction to heavy (high-density) crude oil (suitable for co-combustion in coal power stations) and light (low-density) crude oil, which can be upgraded by hydrodeoxygenation (HDO) to biofuels.

The *rapid thermal processing* process (RTP™ process) occurs at a temperature of approximately 500°C (930°F), when a turbulent stream of hot sand flashes the biomass into a vapor. The vapor is then rapidly condensed into a liquid. This process occurs in less than two seconds, yielding high quantities of bio-oil (typically 65 to 75% w/w yield of pyrolysis oil from dried lignocellulosic biomass).

Bio-oil is a dark brownish viscous liquid that bears some resemblance to fossil crude oil. However, bio-oil is a complex oxygenated compound comprised of water, water-soluble compounds, such as acids, esters, etc., and water-insoluble compounds, usually called pyrolytic lignin because it comes from the lignin fraction of the biomass. The elemental composition of bio-oil is similar to that of the parent biomass. Because of its high oxygen content, the heating value (Btu per gallon) of bio-oil is lower than fossil fuel, typically only approximately half the heating value of fossil crude such as high-boiling fuel oil. However, it contains less nitrogen and only traces of metals or sulfur.

Bio-oil is acidic with a pH in the 2-4 range, making it highly unstable and corrosive – the acidity can be lessened by the addition of readily available base compounds. It, therefore, presents transportation/piping and storage challenges including the tendency to corrode most metals. Hence, it is usually transported and stored in stainless steel containers.

Like other biofuels, the properties of bio-oil are variable and dependent on the feedstock. The specific gravity of the liquid is approximately 1.10 to 1.25, which means it is slightly heavier than water, heavier than fuel oil, and significantly heavier than the bulk density of the original biomass. The viscosity of the oil varies from as low as 25 cP up to 1,000 cP, depending on the water content and the original feedstock.

Processes are available to crack (thermally decompose) and hydrotreat pyrolysis oil to produce more familiar refined products such as diesel oil, kerosene, and gasoline, but the conversion efficiency and energy efficiency of such cracking is poor, and near or midterm commercialization seems unlikely. An alternative processing strategy is to gasify the pyrolysis oil to produce synthesis gas and then proceed with Fischer-Tropsch catalytic processing to produce a range of refined synfuels—this on the theory that most gasifiers are better able to cope with liquids than solids. The Carbo-V process is an example of a combined pyrolysis-gasification production technology for converting biomass into liquid fuels.

Quality

The term quality (as applied to a gas or liquid stream), is measured by the amount of energy that is obtained from burning a measured volume of the gas or liquid in British thermal units (Btu). The economic value of the gas stream is estimated from the Btu value insofar as the gas stream may have (i) a low Btu value, or (ii) a medium Btu value, or (iii) a high Btu value.

The composition of gas stream with the source from which the gas is produced. The different hydrocarbons that are contained within a gas stream can be separated using their different physical properties as weight, boiling point, or vapor pressure. Depending on its content of heavy components, the gas stream gas can be considered as rich (five or six gallons or more of recoverable hydrocarbons per cubic feet) or lean (less than one gallon of recoverable hydrocarbons per cubic feet).

The energy content of a gas stream is variable and depends on its accumulations, which are influenced by the amount and types of energy gases they contain: the more noncombustible gases in a gas stream, the lower the Btu value. In addition, the volume mass of energy gases that are present in a gas stream accumulation also influences the Btu value of gas stream. The more carbon atoms in a hydrocarbon gas, the higher its Btu value. Btu analyses of gas stream are done at each stage of the supply chain. Gas chromatographic process analyzers are used in order to conduct fractional analysis of the gas stream, separating gas stream into identifiable components. The components and their concentrations are converted into a gross heating value in British thermal units per cubic foot (Btu/ft³).

Typically, a gas stream – as it is when extracted from a process – is not suitable for pipeline transportation or commercial use before being processed. Pipelines set their specifications for the quality of gas stream. In any case, gas stream must be processed in order to remove unwanted water vapor, solids, or other contaminants and to get those hydrocarbons that have a higher value as separate products.

See also: High Btu Gas, Low-Btu Gas, Medium Btu Gas.

Quench

Quenching, rapid cooling, as by immersion in oil or water, of an object or process product from the high temperature at which it has been treated. Quenching can also be referred to as shock cooling as when a (relatively) cool liquid to the hot reactants. An example is the termination of the reactions by adding a quench liquid to the hot products as they merge from a thermal unit. The quench stream reduces the potential for further reaction of the hot visbreaker liquids.

Water quenching is a rapid cooling, where water as a quenching medium extracts heat much faster. While oil as a medium will extract heat much slower, hence the rate of cooling will be slower than water.

In chemistry, the term work-up refers to the series of manipulations (which may be considered to be quenching processes) that are required to isolate and purify the product(s) of a chemical reaction. Typically, these manipulations may include: (i) quenching a reaction to deactivate any unreacted reagents, (ii) cooling the reaction mixture or adding an antisolvent to induce precipitation and collecting or removing the solids by filtration, decantation, or centrifugation, (iii) removal of solvents by evaporation, (iv) separating the reaction mixture into organic and aqueous layers by liquid-liquid extraction, and (v) purification by chromatography, distillation, or recrystallization.

Thus, in an industrial process, quenching is the process of terminating a reaction by suddenly decreasing the temperature of the reactants, thereby reducing the potential for secondary reactions or tertiary reactions that could destroy the integrity and yield of the desired product(s).

In the quenching process (which can be air-quenching or liquid-quenching), the performance of heat transfer relates greatly on the characteristics of air flow or liquid flow, and these characteristics vary with the conditions of interfaces, in particular, the gradients of temperature. Because the conjugate heat transfer is transient, the characteristics of the process may vary with respect to time.

Radiation

Radiation is the emission or transmission of energy in the form of waves or particles through space or through a material medium. Radiation can be produced in one of two ways which are (i) by radioactive decay of an unstable atom (radionuclide), or (ii) by the interaction of a particle with matter. Some attributes of radioactive decay are that it is spontaneous and random, and the type of radiation emitted depends on the specific radionuclide.

Radiation is also often categorized as either ionizing or non-ionizing depending on the energy of the radiated particles. A common source of ionizing radiation is radioactive materials that emit α -radiation, β -radiation, or γ -radiation, consisting of helium nuclei or electrons or positrons, or photons, respectively. The term ionize refers to the breaking of one or more electrons away from an atom, an action that requires the relatively high energies that these electromagnetic waves supply. Further down the spectrum, the non-ionizing lower energies of the lower ultraviolet spectrum cannot ionize atoms, but can disrupt the inter-atomic bonds which form molecules, thereby breaking down molecules rather than atoms. The waves of longer wavelength than ultraviolet light in visible light, infrared, and microwave frequencies cannot break bonds but can cause vibrations in the bonds which are sensed as heat.

Radiation emission as the result of an interaction, on the other hand, depends on both the incoming particle and the material it hits, and is theoretically predictable if enough information is known. Radioactive decay and interactions will be discussed in more detail in the following sections. Radiation is described by its type and energy, and the types of radiation fall into two main categories: (i) particulate and (ii) electromagnetic. Particulate radiation consists of particles that have mass and energy, and may or may not have an electric charge.

On the other hand, electromagnetic radiation consists of photons that have energy, but no mass or charge. A photon (sometimes referred to as a packet of light), as described by quantum theory, is a particle or quantum that contains a discrete quantity of electromagnetic energy which travels at the speed of light, or 3×10^8 meters per second. Visible light, ultraviolet light, x-rays, and gamma rays are all photons.

See also: Radioactive Decay, Radioactivity.

Radiation – Types

There are several types of radiation present in nature and anthropogenic sources: (i) alpha particles, (ii) beta particles, (iii) gamma rays, (iv) x-rays, and (v) neutrons. A radioactive atom sooner or later will emit radiation in order to attain a more stable state. In some cases, it turns out that the daughter nucleus is also unstable – and consequently will emit another particle. Thus, there is a series of radioactive atoms of which uranium is the most common example. The starting point is the uranium-238 (^{238}U) isotope which decays through 14 steps and results in the production of the stable lead-206 isotope (^{206}Pb) (Table R-1).

Table R-1 The uranium-radium series.

Isotope	Radiation Type	Half-life
Uranium-238	Alpha	4.47 billion years
Thorium-234	Beta	24.21 days
Protoactinium-234	Beta	1.17 minutes
Uranium-234	Alpha	245,000 years
Thorium-230	Alpha	77,000 years
Radium-226	Alpha	1,600 years
Radon-222	Alpha	3.82 days
Polonium-218	Alpha	3.05 minutes
Lead-214	Beta	26.8 minutes
Bismuth-214	Beta	19.8 minutes
Polonium-214	Alpha	0.164 milliseconds
Lead-210	Beta	22.3 years
Bismuth-210	Beta	5.01 days
Polonium-210	Alpha	138.4 days
Lead 206	N/A	Stable

Radon (a noble gas) and the radon decay products (the 5 isotopes from radon-222 to and including polonium-214) have short half-lives.

Alpha Particles

Alpha particles are the slowest of the different types of radiation. They can travel only a few inches in the air, losing their energy almost as soon as they collide with anything. They can easily be shielded with a sheet of paper or the outer layer of a person's skin. An alpha particle has a large mass and two protons and no electrons. Because it has two protons and no electrons, it is positively charged. When emitted from the nucleus, the positive charge causes the alpha particle to strip electrons from nearby atoms as it passes.

An α -particle is the nucleus of helium. It has a charge of +2 and a weight of 4 atomic mass units. The “mother” nucleus (M) is changed into a “daughter” nucleus (D) according to the following reaction:

A is the atomic mass, i.e., the number of protons and neutrons, and Z is the atomic number, i.e., the number of protons.

The emitted alpha-particles all have the same energy, or are distributed in a few mono-energetic groups. The energy is high – ranging from 1.5 MeV to about 11 MeV. Almost all α -particle sources are found among the heavy elements, and most of them are natural. The daughter nucleus is very often unstable – and most often emits gamma radiation.

An alpha particle is identical in makeup to the nucleus of a helium atom, consisting of two neutrons and two protons. Alpha particles have a positive charge and have little or no penetrating power in matter. They are easily stopped by materials such as paper and have a range in air of only an inch or so. Naturally occurring radioactive elements such as uranium and radon daughters emit alpha radiation.

Alpha particles are extremely hazardous to fire fighters because they can be inhaled and deposited in body tissues, where they can cause severe long-term health effects. Positive pressure is effective protection against inhaling alpha particles. These agents can affect the cells of the body in various ways, and each is capable of destroying cells.

Alpha decay is the process in which an isotope releases a helium nucleus (2 protons and 2 neutrons) and thus decays into an atom with two less protons.

Beta Particles

Beta particles are more energetic than alpha particles and can travel in the air for a distance of a few feet. Beta particles can pass through a sheet of paper but may be stopped by a sheet of aluminum foil or glass. A beta particle has a small mass and is usually negatively charged. It is emitted from the nucleus of an atom with a charge of minus one. Beta radiation causes ionization by interfering with electrons in their orbits. Both have a negative charge, so the electrons are repelled when the beta particle passes.

An unstable nucleus may attain a more stable configuration by emitting a β -particle. In this process, a neutron in the nucleus is transformed into a proton and an electron (see illustration). Due to the difference in mass, a neutron is sometimes considered to be a proton + an electron + a small subatomic particle (the *neutrino*).

Both natural sources and artificial radioactive sources may be β -particle emitters. The energy of the emitted β -particle is usually much smaller than that of the α -particles. Furthermore, the energy of the β -particles varies from one disintegration to another! In fact, β -particle emission involves a whole spectrum of energies. The reason for this situation is that together with the β -particle, a tiny neutral particle (a neutrino) is emitted. Thus:

In this process, the mass A is unchanged and the proton number (Z) increases by one.

The kinetic energy of the β -particle and the neutrino combined is constant. The energy of the β -particle alone varies from zero up to a maximum value – equal to the constant. The average energy of the β -particle is on the order of 33% of this maximum energy.

Thus, beta radiation is composed of particles that are identical to electrons. As a result, beta particles have a negative charge. Beta radiation is slightly more penetrating than alpha but may be stopped by materials such as aluminum foil and panels composed of Lucite (an acrylic plastic resin). The particles have a range in air of several feet. Naturally occurring radioactive elements such as potassium-40 (^{40}K) emit beta radiation. Beta particles can damage the skin or tissues of the eye. Internally, they can be extremely damaging if they concentrate in specific tissues.

Beta decay is the process in which one of the neutrons in an isotope decays, leaving a proton, electron, and anti-neutrino. As a result, the nucleus decays into an atom that has the same number of nucleons, with one neutron replaced by a proton. Beta positive decay is the reverse process, in which a proton decays into a neutron, anti-electron, and neutrino.

Gamma Rays

Gamma rays (unlike alpha or beta particles) are waves of pure energy; they have no mass. They are emitted from the nucleus of an atom and travel at the speed of light (186,000 miles per second). Gamma radiation can be very penetrating and requires concrete, lead, or steel to stop it.

Gamma radiation is a form of electromagnetic radiation, like radio waves or visible light, but with a much shorter wavelength. It is more penetrating than alpha or beta radiation, capable of passing through dense materials such as concrete. X-rays are similar to gamma radiation.

Gamma decay is the process in which an excited atomic nucleus kicks out a photon and releases some of its energy. The makeup of the nucleus doesn't change; it just loses energy.

*Neutron Particles*

Neutrons are particles normally contained in the nucleus of an atom. They can be released through certain manufacturing processes, such as nuclear fission (splitting an atomic nucleus).

Neutrons are considerably larger than beta particles but have only one-fourth the mass of an alpha particle. Because they can penetrate even thick lead shields, they can be extremely damaging to humans. However, neutron radiation is rare since it is generally emitted only when atomic weapons are detonated.

X-rays

X-rays are essentially the same as gamma rays except that they are emitted from the electrons that orbit the atom's nucleus, rather than from the nucleus itself. Gamma rays and X-rays are also called photons. Because they have high energy and penetrate deeply, gammas and X-rays can affect not only specific organs, but the surrounding tissues as well.

Gamma radiation and X-rays are electromagnetic waves or photons and have no electrical charge. The difference between the two is that gamma rays originate inside the nucleus and X-rays originate outside the nucleus. Both can ionize an atom by directly interacting with the electrons.

Radioactive Decay

Radionuclides are inorganic chemicals that emit radiation because their atoms are unstable and they disintegrate or decay as they release energy in the form of radioactive particles or waves. There are many different types of radioactive decay. A decay, or loss of energy from the nucleus, results when an atom with an initial type of nucleus (the parent radionuclide or parent radioisotope) transforms into a daughter nuclide. The transformation produces an atom in a different state (a nucleus containing a different number of protons and neutrons). In some decay processes, the parent and the daughter nuclides are different chemical elements, and thus the decay process results in the creation of an atom of a different element (nuclear transmutation). Another type of radioactive decay results in products that are not defined, but appear in a range of molecular fragments of the original nucleus (spontaneous fission) which occurs when a large unstable nucleus spontaneously splits into two (and occasionally three) smaller daughter nuclei, and generally leads to the emission of gamma rays, neutrons, or other particles from those products.

Unlike other inorganic elements or chemicals, radionuclides degrade naturally, but the degradation process itself is hazardous to living things. The risk posed by radionuclides is a function of the type and amount of radiation, as well as exposure pathways. The half-life (the time required to reduce the concentration of a chemical to 50% of the initial concentration) of a radioactive element (Table R-2). Moreover, the radioactive half-life for a given radioisotope is a measure of the tendency of the nucleus to decay (disintegrate) and is based upon that probability.

Table R-2 Examples of the half-life of several elements and isotopes.

Isotope	Half-life
Carbon-11	20.4 minutes
Carbon-12	5,730 years
Cesium-137	30.2 years
Cobalt-60	5.27 years
Iodine-123	13.2 hours
Iodine-131	8.05 days
Oxygen-15	2.02 minutes
Phosphorus-32	14.3 days
Potassium-40	1.3 billion years
Radon-222	3.82 days
Strontium-90	28.2 years
Sulfur-35	87.4 days
Thallium-201	3.04 days
Thorium-232	14 billion years
Tritium	12.3 years
Uranium-235	704 million years
Plutonium-239	24,100 years

The half-life is independent of the physical state (solid, liquid, gas), temperature, pressure, the chemical compound in which the nucleus exists, and essentially any other outside influence. The half-life is also independent of the chemistry of the atomic surface, and independent of the ordinary physical factors of the environment in which the chemical exists.

Radioactive Isotopes

Matter is composed of atoms whose nuclei contain protons and neutrons. Many elements which are found within the Earth system exist in different atomic configurations (isotopes) which have same atomic number but differ in their atomic mass. A radioactive isotope (also called a radioisotope, a radionuclide, or a radioactive nuclide) is any of several species of the same chemical element with different masses in which the nuclei are unstable and dissipate excess energy by spontaneously emitting radiation in the form of alpha, beta and gamma rays. These unstable elements decay by emission of energy; such isotopes, which emit radiation, are the radioactive isotopes (also referred to as radioisotopes).

The number of protons in the nuclei determines whether the atom is hydrogen, carbon, uranium, oxygen, or one of the other 115 currently known elements. For example, most carbon atoms will have 6 protons and 6 neutrons. Atoms of the same element, however, may have different numbers of neutrons in their nuclei. The various forms of an element that differ only in the number of neutrons are referred to as isotopes; one element may have many different isotopes. Some carbon atoms have five, seven, or eight neutrons. Since an isotope is identified by the element name and its atomic weight (i.e., the sum of the protons and neutrons in each atom), carbon atoms with six neutrons

in their nuclei (the dominant form) have an atomic weight of $6+6=12$ and are referred to as carbon-12. Carbon atoms with five, seven, or eight neutrons in their nuclei are referred to as carbon-11, carbon-13, and carbon-14, respectively. Isotopes of the same element generally have virtually identical chemical characteristics but may differ in other ways. For example carbon-12 is stable whereas carbon-14 is unstable, or radioactive. Stable isotopes maintain their nuclear structure without changing over time. Radioactive isotopes, referred to as radioisotopes or radionuclides, have unstable nuclei which spontaneously disintegrate and release energy in the process to form other nuclear particles that can be detected by a radioactivity-measuring instrument.

See also: Radiation, Radioactive Decay.

Radioactive Metals

The term radioactive metals refers to natural and synthetic metals that can release alpha (α), beta (β), and gamma (γ) rays. These metals fall into a group of radioactive elements (Table R-3), some of which can be put to usage in many ways for the benefit of human beings, such as power generation, nuclear battery, material engineering, and treatment of cancer.

Table R-3 List of radioactive elements*.

Element, symbol, atomic number	Most Stable Isotope	Half-life*
Technetium, Tc, 43	Tc-91	4.21×10^6 years
Promethium, Pm, 61	Pm-145	17.4 years
Polonium, Po, 84	Po-209	102 years
Astatine, At, 85	At-210	8.1 hours
Radon, Rn, 86	Rn-222	3.82 days
Francium, Fr, 87	Fr-223	22 minutes
Radium, Ra, 88	Ra-226	1600 years
Actinium, Ac, 89	Ac-227	21.77 years
Thorium, Th, 90	Th-229	7.54×10^4 years
Protoactinium, Pa, 91	Pa-231	3.28×10^4 years
Uranium, U, 92	U-236	2.34×10^7 years
Neptunium, Np, 93	Np-237	2.14×10^6 years
Plutonium, Pu, 94	Pu-244	8.00×10^7 years
Americium, Am, 95	Am-243	7370 years
Curium, Cm, 96	Cm-247	1.56×10^7 years
Berkelium, Bk, 97	Bk-247	1380 years
Californium, Cf, 98	Cf-251	898 years
Einsteinium, Es, 99	Es-252	471.7 days
Fermium, Fm, 100	Fm-257	100.5 days
Mendelevium, Md, 101	Md-258	51.5 days
Nobelium, No, 102	No-259	58 minutes

(Continued)

Table R-3 List of radioactive elements*. (Continued)

Element, symbol, atomic number	Most Stable Isotope	Half-life*
Lawrencium, Lr, 103	Lr-262	4 hours
Rutherfordium, Rf, 104	Rf-265	13 hours
Dubnium, Db, 105	Db-268	32 hours
Seaborgium, Sg, 106	Sg-271	2.4 minutes
Bohrium, Bh, 107	Bh-267	17 seconds
Hassium, Hs, 108	Hs-269	9.7 seconds
Meitnerium, Mt, 109	Mt-276	0.72 seconds
Darmstadtium, Ds, 110	Ds-281	11.1 seconds
Roentgenium, Rg, 111	Rg-281	26 seconds
Copernicium, Cn, 112	Cn-285	29 seconds
Nihonium, Nh, 113	Nh-284	0.48 seconds
Flerovium, Fl, 114	Fl-289	2.65 seconds
Moscovium, Mc, 115	Mc-289	87 milliseconds
Livermorium, Lv, 116	Lv-293	61 milliseconds
Tennessine, Ts, 117	Ts-294	51 milliseconds
Oganesson, Og, 118	Og-294	1.8 milliseconds

*Many of these elements (Americium to Oganesson, atomic numbers 95 to 118) are synthetic insofar as they do not occur naturally and have only been created in the laboratory.

Radioactivity is a natural part of the environment of the Earth which contains several primordial long-lived radioisotopes that have survived to the present in significant amounts. Potassium-40 (^{40}K), with a 1.3 billion-year half-life, has the lowest mass of these isotopes and beta decays to both argon-40 (^{40}Ar) and calcium-40 (^{40}Ca). Many isotopes can decay by more than one method. Three high atomic number elements: thorium-232 (^{232}Th , with a 14.1 billion year half-life), uranium-235 (^{235}U , with a 700 million year half-life), and uranium-238 (^{238}U , with a 4.5 billion year half-life) decay through emission of alpha and beta decays ending at the stable lead-208 (^{208}Pb), lead-207 (^{207}Pb), and lead-206 (^{206}Pb), respectively. The current ratio of uranium to lead present on Earth gives an estimate of the age of the Earth at 4.5 billion years (4.5×10^9 years). One of the intermediate products of the uranium-238 decay chain, radon-222 (^{222}Rn) with a half-life of 3.8 days, is responsible for higher levels of background radiation in many parts of the world – primarily because radon is a gas and can easily seep out of the earth into unfinished basements and then into the house. Some radioactive isotopes, for example carbon-14 (^{14}C) and beryllium-7 (^7Be), are produced continuously through reactions of cosmic rays (high-energy charged particles from outside the Earth) with molecules in the upper atmosphere.

Also, the study of radioactivity is important to understand the structure of the Earth because radioactive decay heats the interior of the Earth to high temperatures giving rise to geothermal heat and energy.

See also: Geothermal Energy.

Radioactive Waste

Radioactive waste is produced at all stages of the nuclear fuel cycle, from the initial mining of the uranium to the final disposal of the spent fuel from the reactor. The term *radioactive waste* encompasses a broad range of material with widely varying characteristics. Some radioactive waste is barely radioactive and safe to handle, whereas other

types are intensely hot and highly radioactive. For example, some radioactive wastes decay to safe levels of radioactivity in a matter of days or weeks, whereas other types will remain dangerous for thousands of years.

Disposal

Disposal is the final step in the management of radioactive waste. The aim is to provide safety through emplacement of waste in facilities designed for appropriate levels of containment and isolation. However, the proper disposal of radioactive waste is still highly challenging and is one of the most difficult kinds of waste to manage because of the hazardous nature of the waste and such waste is required to be very carefully stored or reprocessed.

In fact, with the continued interest in generating energy from alternative sources such as, in this context, nuclear sources, the challenge of making nuclear power safer does not end after the power has been generated. The nuclear fuel remains dangerously radioactive for thousands of years after it is no longer useful in a commercial reactor. The resulting waste disposal problem has become a major challenge for the industry.

Disposing radioactive waste is unquestionably one of the major problems associated with the development of nuclear power; radioactive waste is also a by-product of nuclear weapons plants, hospitals, and scientific research. Even though federal policy is based on the assumption that radioactive waste can be disposed of safely, new storage and disposal facilities for all types of radioactive waste have frequently been delayed or blocked by concerns about safety, health, and the environment.

The highly toxic wastes must be isolated from the environment until the radioactivity decays to a safe level. In the case of plutonium, for example, the half-life is twenty-six thousand years. At that rate, it will take at least one hundred thousand years before radioactive plutonium is no longer dangerous. Any facilities built to store such materials must last at least that long.

High-Level Waste

High-level radioactive wastes are the highly radioactive materials produced as a by-product of the reactions that occur inside nuclear reactors. High-level waste takes one of two forms: (i) spent (used) reactor fuel when it is accepted for disposal and (ii) waste material remaining after spent fuel is reprocessed.

Uranium fuel can be used for twelve to eighteen months, after which it is no longer as efficient in splitting its atoms and producing the heat needed to generate electricity. It must be removed from the reactor and replaced with fresh fuel. Some of the spent fuel is reprocessed to recover the usable uranium and plutonium, but the radioactive material that remains is dangerous for thousands of years.

Safe methods for the final disposal of high-level radioactive waste are technically proven; the international consensus is that geological disposal is the best option.

Low-Level Waste

Low-level waste, which contains lesser levels of radioactivity, includes trash (such as wiping rags, swabs, and syringes), contaminated clothing (such as shoe covers and protective gloves), and hardware (such as luminous dials, filters, and tools). This waste comes from nuclear reactors, industrial users, government users (but not nuclear weapon sites), research universities, and medical facilities. In general, low-level waste decays relatively quickly (in ten to one hundred years).

A somewhat lower-level (than high-level) hazardous type of radioactive waste is waste that has been exposed to alpha radiation, or that contains long-lived radionuclides in concentrations that require isolation and containment for periods beyond several hundred years, is classified as intermediate-level radioactive waste. This type of waste includes resins, chemical sludge, and metal nuclear fuel cladding, as well as contaminated materials from reactor decommissioning. For disposal, this type of waste may be solidified in concrete or bitumen or mixed with silica sand and vitrified, although this method is not without some risk and danger.

Typically, low- and intermediate-level radioactive wastes are buried in geological repositories. These repositories must isolate the nuclear waste from the biosphere for as long as 100,000 years. For the storage of radioactive waste, the geological formations were used where water-soluble compounds have been accumulated for millions of years, such as salt mines, clay rocks, granite, and tuff. In these geological formations, further engineering barriers are constructed. The nuclear waste is placed into stainless steel or reinforced concrete containers and deposited inside the engineering barrier system. Only solid wastes are stored; liquid wastes are solidified by cementation. The holes

among the containers are filled with cement too. In the geological repositories, there are several barrier systems (rocks, engineering barriers) which one by one must isolate the radioactive waste from the environment.

There are several aspects to take into account when selecting a suitable environment for waste disposal. These are, for example, (i) the hydrological properties of the geological environment, (ii) the potential corrosion and erosion of the engineering barrier system, (iii) leaching, and migration of the radionuclide in the geological environment. In addition, the microbiological activity and the effects of radiolysis must be considered.

In the corrosion and microbiological degradation of these substances, gaseous product may be released. The corrosion produces hydrogen, while the microbiological processes transform the organic substances of the nuclear wastes into carbon dioxide or methane, depending on the redox conditions. The gases can have unfavorable effects during storage. For example, the increasing pressure can push the radioactive gases and solutions into the environment. As a result of the cementation, the pH of the pore solution is set above 12 which inhibits the corrosion of the containers and the microbiological activity, decreasing the rate of gas release.

The leaching and migration of radionuclides is the overall effect of hydrological, interfacial (adsorption, ion exchange), and chemical processes (hydrolysis, precipitation, redox reactions). The interactions are determined by the surface charge of minerals and rocks, and the chemical species of the radioactive isotopes.

Mixed Waste

Mixed waste is high-level, low-level, or transuranic waste that also contains hazardous nonradioactive waste. Such waste poses serious institutional problems because of the radioactive portion. Such waste must be handled carefully and sent for disposal according to the laws and regulations of the necessary authorizes.

Transuranic Waste

Transuranic waste is a by-product of weapons production, nuclear research, and power production, and consists of protective gear, tools, residue, debris, and other items contaminated with small amounts of radioactive elements (mainly plutonium). Transuranic waste includes the eleven man-made radioactive elements with atomic numbers greater than that of uranium (ninety-two) and therefore beyond (*trans-*) uranium (*-uranic*) on the Periodic Table of the elements. The half-lives (the time it takes for half the radioisotopes present in a sample to decay to nonradioactive elements) of these elements are on the order of thousands of years.

Uranium Mill Tailings

Uranium mill tailings are primarily the sandy process waste material from a conventional uranium mill. This ore residue contains the radioactive decay products from the uranium chains (mainly the uranium-238, ^{238}U , chain) and heavy metals.

Even though the tailings may emit low levels of radiation, the large volume of the material poses a hazard, particularly from radon emissions and groundwater contamination. The dangers of uranium mill tailings were not realized until the early 1970s, so many miners and residents of the western United States were exposed to them. Cancer incidences are high among miners who worked before the 1970s.

See also: Periodic Table of the Elements.

Radioactivity

Radioactivity is the spontaneous emission of energy and/or high-energy particles from the nucleus of an atom. One type of radioactivity is produced naturally and is emitted by radioactive isotopes (or radioisotopes), such as radioactive carbon (carbon 14, or C-14) and radioactive hydrogen (H-3, or tritium). The energy and high-energy particles that radioactive isotopes emit include alpha rays, beta rays, and gamma rays.

In nature, the nuclei of most atoms are stable. However, certain atoms have unstable nuclei due to an excess of either protons or neutrons, or an excess of both. They are described as radioactive, and are known as radioisotopes or radionuclides.

The nuclei of radioactive atoms change spontaneously into other atomic nuclei, which may or may not be radioactive. For instance, uranium-238 (^{238}U) changes into a succession of different radioactive nuclei until it reaches a

stable form, lead-206 (^{206}Pb) (Table R-1). This irreversible transformation of a radioactive atom into a different type of atom is known as disintegration. It is accompanied by the emission of different types of radiation. A chemical element can therefore have both radioactive isotopes and non-radioactive isotopes. For example, carbon-12 is not radioactive, but carbon-14 is. Because radioactivity only affects the nucleus and not the electrons, the chemical properties of radioactive isotopes are the same as those of stable isotopes.

In radioactive processes, particles or electromagnetic radiation are emitted from the nucleus. A radioactive atom possesses an unstable nucleus. This means that radioactive atoms will emit radiation sooner or later and by this convert into a more stable state that can be represented simply as:

Thus, the most common forms of radiation that may be emitted are (i) alpha (α), (ii) beta (β), and gamma (γ) radiation.

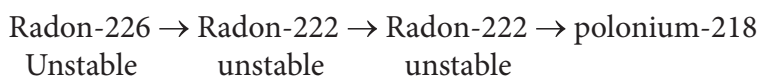

Nuclear radiation occurs in other forms, including the emission of protons or neutrons or spontaneous fission of a massive nucleus. Of the nuclei found on Earth, the vast majority is stable. This is so because almost all short-lived radioactive nuclei have decayed during the history of the Earth. There are approximately 270 stable isotopes and 50 naturally occurring radioisotopes (radioactive isotopes). Thousands of other radioisotopes have been made in the laboratory.

Radioactive decay will change one nucleus to another if the product nucleus has a greater nuclear binding energy than the initial decaying nucleus. The excess binding energy appears as kinetic energy or rest mass energy of the decay products. However, nuclear decay processes must satisfy several conservation laws, meaning that the value of the conserved quantity after the decay, taking into account all the decay products, must equal the same quantity evaluated for the nucleus before the decay.

The probability that a particular nucleus will undergo radioactive decay during a fixed length of time does not depend on the age of the nucleus or how it was created. Although the exact lifetime of one particular nucleus cannot be predicted, the mean (or average) lifetime of a sample containing many nuclei of the same isotope can be predicted and measured. A convenient way of determining the lifetime of an isotope is to measure how long it takes for one-half of the nuclei in a sample to decay—this quantity is called the half-life, $t_{1/2}$. Of the original nuclei that did not decay, half will decay after another half-life, leaving one-quarter of the original sample after a total time of two half-lives. After three half-lives, one-eighth of the original sample will remain and so on. Measured half-lives vary from tiny fractions of seconds to billions of years, depending on the isotope.

In the process of alpha decay, the nucleus emits a ^4He nucleus, an alpha particle. Alpha decay occurs most often in massive nuclei that have too large a proton-to-neutron ratio. An alpha particle, with its two protons and two neutrons, is a very stable configuration of particles. Alpha radiation reduces the ratio of protons to neutrons in the parent nucleus, bringing it to a more stable configuration. Nuclei, which are more massive than lead, frequently decay by this method.

As an example, Radium (atomic number 88) has an unstable nucleus weighing 226 atomic units. It decays by emitting an α -particle and becomes a new element radon (^{222}Rn , atomic number 86). Radon-226 is however unstable and will in turn decay into polonium (^{218}Po).

Thus, in alpha decay, the atomic number changes, so the original (or parent) atoms and the decay-product (or daughter) atoms are different elements and therefore have different chemical properties. In the alpha decay of a nucleus, the change in binding energy appears as the kinetic energy of the alpha particle and the daughter nucleus.

Because this energy must be shared between these two particles, and because the alpha particle and daughter nucleus must have equal and opposite momenta, the emitted alpha particle and recoiling nucleus will each have a well-defined energy after the decay. Because of the smaller mass, most of the kinetic energy goes to the alpha particle.

Beta decay occurs when, in a nucleus with too many protons or too many neutrons, one of the protons or neutrons is transformed into the other. In beta-minus decay, a neutron decays into a proton, an electron, and an antineutrino:

In beta plus decay, a proton decays into a neutron, a positron, and a neutrino:

Both reactions occur because one or the other will move the product closer to the region of stability. These particular reactions take place because conservation laws are obeyed. Electric charge conservation requires that if an electrically neutral neutron becomes a positively charged proton, an electrically negative particle (in this case, an electron) must also be produced. Similarly, conservation of lepton number requires that if a neutron (lepton number = 0) decays into a proton (lepton number = 0) and an electron (lepton number = 1), a particle with a lepton number of -1 (in this case an antineutrino) must also be produced. The leptons emitted in beta decay did not exist in the nucleus before the decay—they are created at the instant of the decay.

An isolated proton (i.e., a hydrogen nucleus with or without an electron) does not decay. However, within a nucleus, the beta decay process can change a proton to a neutron. An isolated neutron is unstable and will decay with a half-life of 10.5 minutes. A neutron in a nucleus will decay if a more stable nucleus results; the half-life of the decay depends on the isotope. If it leads to a more stable nucleus, a proton in a nucleus may capture an electron from the atom (electron capture), and change into a neutron and a neutrino.

Proton decay, neutron decay, and electron capture are three ways in which protons can be changed into neutrons or vice-versa; in each decay, there is a change in the atomic number, so that the parent and daughter atoms are different elements. In all three processes, the number A of nucleons remains the same, while both proton number, Z, and neutron number, N, increase or decrease by 1. In beta decay, the change in binding energy appears as the mass energy and kinetic energy of the beta particle, the energy of the neutrino, and the kinetic energy of the recoiling daughter nucleus. The energy of an emitted beta particle from a particular decay can take on a range of values because the energy can be shared in many ways among the three particles while still obeying energy and momentum conservation.

In gamma decay, a nucleus changes from a higher energy state to a lower energy state through the emission of electromagnetic radiation (photons). The number of protons (and neutrons) in the nucleus does not change in this process, so the parent and daughter atoms are the same chemical element. In the gamma decay of a nucleus, the emitted photon and recoiling nucleus each have a well-defined energy after the decay. The characteristic energy is divided between only two particles.

The units of radioactivity relate to the number of decays per second, or activity, from a sample of radioactive nuclei is measured in becquerel (Bq, named after Henri Becquerel), and one decay per second equals one becquerel. An older unit is the curie (named after Pierre and Marie Curie), and one curie is approximately the activity of 1 gram of radium and equals (exactly) 3.7×10^{10} becquerel. The activity depends only on the number of decays per second, not on the type of decay, the energy of the decay products, or the biological effects of the radiation.

See also: Radioactive Decay.

Radionuclides

A radionuclide (also called radioactive nuclide, radioisotope, or radioactive isotope) is an unstable atom because of excess nuclear energy. This excess energy can be used in one of three ways: (i) emitted from the nucleus as gamma radiation, (ii) transferred to one of the electrons to release it as a converted electron, or (iii) used to create and emit new particles, such as an alpha particle or a beta particle from the nucleus. These emissions are sufficiently powerful

to liberate an electron from another atom. The radioactive decay can produce a stable nuclide or will sometimes produce a new unstable radionuclide which may undergo further decay.

Because of the unstable nucleus, a radionuclide is a radioactive element that is typically referred to by a name followed by a number, for example cesium-137 (Cs-137 or ^{137}Cs ; Cs is the chemical symbol for cesium as it appears in the Periodic Table of the Elements). The number following the name of the element is the mass of the element and is equal to the total number of particles contained in the nucleus of the atom.

Exposure to radionuclides generally has a harmful effect on living organisms including humans, although low levels of exposure occur naturally without harm. The degree of harm will depend on the nature and extent of the radiation produced, the amount and nature of exposure (close contact, inhalation, or ingestion), and the biochemical properties of the element, with increased risk of cancer as the most usual consequence. However, radionuclides with suitable properties are used in nuclear medicine for both diagnosis and treatment.

Rankine Cycle

The Rankine cycle is the thermodynamic cycle for the steam turbine and is the basis for conventional power-generating stations and consists of a heat source (boiler) that converts water to high-pressure steam.

In the steam cycle, water is first pumped to elevated pressure, which is medium-to- high pressure, depending on the size of the unit and the temperature to which the steam is eventually heated. It is then heated to the boiling temperature corresponding to the pressure, boiled (heated from liquid to vapor), and then most frequently superheated (heated to a temperature above that of boiling). The pressurized steam is expanded to lower pressure in a turbine, then exhausted either to a condenser at vacuum conditions, or into an intermediate temperature steam distribution system that delivers the steam to the industrial or commercial application. The condensate from the condenser or from the industrial steam utilization system is returned to the feedwater pump for continuation of the cycle.

Thus, there are four processes in the Rankine cycle which are (i) a process in which the working fluid is pumped from low to high pressure; as the fluid is a liquid at this stage, the pump requires little input energy, also known as the isentropic compression process, (ii) a process in which the high-pressure liquid enters a boiler, where it is heated at constant pressure by an external heat source to become a dry saturated vapor; in this segment of the cycle, also known as constant pressure heat addition in boiler, (iii) a process in which the dry saturated vapor expands through a turbine thereby generating power – this decreases the temperature and pressure of the vapor, and some condensation may occur; this is also known as isentropic expansion, and (iv) a process in which the wet vapor enters a condenser where it is condensed at a constant pressure to become a saturated liquid – also known as constant pressure heat rejection in condenser.

In an ideal Rankine cycle, the pump and turbine would be isentropic insofar as the pump and turbine would generate no entropy and hence maximize the net-work output. However, the actual vapor power cycle may differ from the ideal Rankine cycle because of irreversibility in the inherent components caused by fluid friction and heat loss to the surroundings – fluid friction causes pressure drops in the boiler, the condenser, and the piping between the components, and as a result, the steam leaves the boiler at a lower pressure while heat loss reduces the net-work output and, as a result, heat addition to the steam in the boiler is required to maintain the same level of net-work output.

Rapeseed

Rapeseed (*Brassica napus*), also known as rape oil, oilseed rape, and, in the case of one particular group of cultivars, canola, is a bright-yellow flowering member of the family Brassicaceae (mustard or cabbage family), cultivated mainly for its oil-rich seed. It is the third-largest source of vegetable oil and second-largest source of protein meal in the world. There are two subspecies: (i) *Brassica napus* ssp. *Napobrassica*, also known as the swedes rape and (ii) *Brassica napus* ssp. *Napus* which includes the winter and spring oilseed, vegetable, and fodder rape forms. The *pabularia* variety (Siberian kale) is a distinct leaf rape form of the *napus* subspecies which used to be common as a winter-annual vegetable. Rapeseed can be cultivated on a wide variety of well-drained soils, preferably at a pH between 5.5 and 8.3, and has a moderate tolerance of soil salinity.

Rapeseed oil is one of the oldest known vegetable oils, but historically was used in limited quantities due to high levels of erucic acid, which is damaging to cardiac muscle of animals, and glucosinolate derivatives, which made it less nutritious in animal feed. Rapeseed oil can contain up to 54% w/w erucic acid.

Rapeseed oil is used as diesel fuel, either as biodiesel, straight in heated fuel systems, or blended with crude oil distillates for powering motor vehicles. Biodiesel may be used in pure form in newer engines without engine damage and is frequently combined with crude oil-derived diesel in ratios varying from 2% to 20% v/v biodiesel. Owing to the costs of growing, crushing, and refining rapeseed biodiesel, rapeseed-derived biodiesel from new oil costs more to produce than standard diesel fuel, so diesel fuels are commonly made from the used oil. Rapeseed oil is the preferred oil stock for biodiesel production in most of Europe, accounting for approximately 80% v/v of the feedstock, partly because rapeseed produces more oil per unit of land area compared to other oil sources, such as soybeans, but primarily because canola oil has a significantly lower gel point than most other vegetable oils.

In agriculture, canola is a variety of rapeseed oil, or the oil produced from those varieties. Canola is a trademark for a hybrid variety of rape initially bred in Canada. Rapeseed oil was produced in the 19th century as a source of a lubricant for steam engines, and the oil has a bitter taste due to high levels of acids. Canola has been bred to reduce the amount of acid, yielding a more palatable oil.

Rapeseed oil is used in the manufacture of biodiesel for powering motor vehicles. Biodiesel may be used in pure form in newer engines without engine damage, and is frequently combined with fossil-fuel diesel in ratios varying from 2% to 20% biodiesel. Formerly, owing to the costs of growing, crushing, and refining rapeseed biodiesel, rapeseed-derived biodiesel costs more to produce than standard diesel fuel. Rapeseed oil is the preferred oil stock for biodiesel production in most of Europe, partly because rapeseed produces more oil per unit of land area compared to other oil sources, such as soy beans.

There is, however, concern over the use of rapeseed for use as biodiesel because rapeseed is currently grown with a high level of nitrogen-containing fertilizers and the manufacture of these generates nitrous oxide (N_2O), a potent greenhouse gas with 296 times the global warming potential of carbon dioxide. It has been estimated that 3 to 5% of nitrogen provided as fertilizer for rapeseed is converted to nitrous oxide.

See also: Biodiesel, Biomass – Extraction.

Rapeseed Methyl Ester

Rapeseed methyl ester is a methyl ester of natural fatty acids (predominantly the C18 fatty acid). The product is an excellent solvent with good biodegradability and toxicity properties (benign toxicity in case of ingestion or contact).

The methyl esters of rapeseed oil are important alternative diesel fuels based on renewable sources. A discontinuous plant production of the methyl esters involves a two-stage low-temperature transesterification of cold-pressed rapeseed oil with methanol at temperatures up to 70°C (158°F). The total methanol-acyl molar ratio of 4:3, with an optimum distribution of methanol between the two stages and a 4% sodium hydroxide in methanol as the catalyst. The final treatment of methyl ester with phosphoric acid and ammonia provides for an exchange of ashy soap forms in the ester for ashless forms, thus rendering the methyl ester as a non-corrosive product.

See also: Biomass – Extraction, Rapeseed.

Rate of Reaction

The rate of reaction is the rate at which the moles or mass of reactants are depleted or products formed with respect to time per unit volume (or per unit weight or surface of catalyst in case of solid-catalyzed reactions) of the reactor. Thus:

$$r_A = (1/V)(dN_A/dt) = dC_A/dt$$

N_A is the moles of A in the reactor at any time, t is the time in seconds, and V is the volume of the reactor. From concentration of reactant A data taken for different reaction time, the rate can be evaluated from the above relation. The rate is also conveniently expressed as a function of C_A :

$$r_A = kC_A^n$$

in this equation, n is the order of reaction and may be any value positive or negative integer that is specific for the reaction which may be first order ($n = 1$), second order ($n = 2$), third order ($n = 3$), and even fractional order; many reactions also manifest a more complicated reaction order, especially the multiple or reversible reactions.

Reactor Types

Chemical reactors (reactors, reactor vessels) are used widely in the various energy oriented industries to purify feedstocks and convert feedstocks into products. This is naturally facilitated by chemical reactions. The choicer of the reactor is dictated by the nature of the reaction and the reaction parameters – high pressure or low pressure, high temperature or low temperature. The classification of the reactor type is mainly based on the number of phases present in the reactor since the character of reactive phases to a large extent decides the physical configuration of reactor equipment (Table R-4).

Furthermore, homogeneous or homogeneously catalyzed reactions can be facilitated in a simple tube or tank reactors, but for heterogeneous catalytic reactions, the reactor typically has a solid catalyst phase, which is not consumed as the reaction takes place. Thus, heterogeneous catalytic reactions are commonly carried out in packed bed reactors, in which the reacting gas or liquid flows through a catalyst bed.

Table R-4 Various reactor-types.

<i>Homogeneous reactors</i> Only one phase (gas or liquid); homogeneous catalyst Examples: tube reactor (plug flow reactor), tank reactor (stirred tank reactor, CSTR), batch reactor, semi-batch reactor.
<i>Heterogeneous catalytic two-phase reactors</i> Two phases: one fluid phase; gas or liquid phase; solid catalyst; reaction takes place on the catalyst surface Examples: packed bed, moving bed, fluidized bed.
<i>Heterogeneous catalytic three-phase reactors</i> Three phases: gas, liquid, and solid catalyst; reaction takes place on the catalyst surface
<i>Gas-liquid reactors</i> A gas phase and a liquid phase; homogenous catalyst; reaction takes place in the liquid phase Examples: absorption column, bubble column, tank reactor, reactive distillation column monolith reactors
<i>Liquid-liquid reactors</i> Two liquid phases; homogeneous catalyst; reaction can take place in both phases Examples: column reactor, mixer-settler reactor.
<i>Fluid-solid reactors</i> Two or three phases; one fluid phase (gas/liquid); one reactive solid phase; reaction between the solid phase and the gas/liquid phase Examples: packed bed, fluidized bed

Fixed bed or slurry bed reactors are the two conventional reactor types currently used for processes. Fixed bed reactors are comparable to the shell and tube heat exchangers that are common in the process industries. In these,

the catalyst, in the form of cylindrical pellets, is contained within 2.5–5 cm (1–2 inch) tubes that are oriented vertically within a large vessel. In the latest fixed bed reactors (for the Fischer-Tropsch process, as an example), these tubes are 1 inch in diameter and approximately 40 feet tall. The biggest challenge with conventional fixed bed reactors lies in controlling the temperature within the reactor tubes. Since some processes (such as the Fischer-Tropsch process) are exothermic and strongly affected by temperature, a hot spot can develop within the center of the tube, resulting in a substantial drop in the catalyst performance. As a result, the performance of fixed bed reactors is limited by heat transfer.

In slurry bed reactors, the catalysts take the form of small particulates (on the order of 50 microns in diameter; 1 micron = $1 \text{ mm} \times 10^{-3} = 1 \text{ meter} \times 10^{-6}$) that are suspended in the liquid wax produced by the reaction. The heat generated by the reaction is removed by coolant tubes that run throughout the reactor.

A micro channel reactor is a reactor that consists of numerous channels with small diameters of less than a few millimeters, and microchannel process technology is used in a range of applications. These include the large number of chemical and process systems that involve thermal processing, ranging from ethane cracking to fuel processing catalytic processes, such as hydrocracking; chemical reactions and production, for example, steam methane reforming and ethylene oxidation; separations, mixing, and emulsification; catalytic processes; gas processing for operations such as hydrogen production; biological and medical applications; and integrated and multi-phase systems. In terms of small-scale distributed biomass-to-liquids production, microchannel reactors offer particular advantages.

For example, because the structure and dynamics of microchannel reactors improves heat transfer between process fluids and channel walls, the biomass-to-liquids process is intensified. In addition, microchannel reactors also allow the use of more active catalysts than conventional systems, which greatly increases the throughput per unit volume of the reactors. The use of microchannel process technology offers a number of advantages in a range of energy and chemical processing applications. These include: (i) improved heat transfer properties and (ii) higher energy efficiency. Microchannel has thin reaction channels which greatly improves heat and mass transfer. This allows optimal temperature control across the catalyst bed, which maximizes catalyst activity and life.

Reburning

Reburning is an effective and economic means of reducing NO_x emissions from all types of industrial and electric utility boilers.

Reburning, or the staged introduction of fuel into a combustion device, is based on laboratory-scale studies in the early 1970s. The first commercial-scale application of this technology to control NO_x emissions was installed in Japan during the same decade. Subsequently, commercial-scale testing was conducted in the U.S. and Europe, mainly on electric utility boilers, but also to some extent on municipal waste incinerators.

Reburning involves the staged addition of fuel into two combustion zones which are (i) the primary combustion zone where coal is fired, and (ii) the reburn zone where additional fuel (the reburn fuel) is added to create a reducing (oxygen-deficient) condition to convert the NO_x produced in the primary zone to molecular nitrogen and water. Above the reburn zone is a burnout zone in which overfire air is added to complete the combustion.

Each zone has a unique stoichiometric air ratio (the ratio of the air used to that theoretically required for complete combustion) as determined by the flows of primary fuel, burner air, reburn fuel, and overfire air.

Coal is fired under normal-to-low excess air conditions at a rate corresponding to 70–90% of the total heat input. The amount of NO_x created in this zone is reduced by approximately 10% because less coal is fired (lower production of fuel NO_x), the heat release rate is lower (lower production of thermal NO_x), and, generally, the excess air level to the burners is reduced (a lower oxygen concentration results in lower emissions of nitrogen oxide(s)).

Reburn fuel injection creates a reducing region within which the reburn fuel molecules break down to hydrocarbon fragments (CH , CH_2 , etc.) that react with NO_x , producing reduced nitrogen species (mainly N_2). The optimum reburn zone stoichiometric ratio is 0.85 to 0.95. This is achieved by injecting reburn fuel at a rate corresponding to 10–30% of the total heat input, depending on the primary zone excess air level. The lower the primary combustion zone excess air, the lower the reburn fuel requirement.

In the burnout zone, overfire air is injected downstream of the reburn zone to complete combustion. Overfire air is typically 20% v/v of the total air flow with an overall excess air level of 15 to 25% being usual. The *overfire air* injection rate is optimized for each specific application to minimize carbon monoxide emissions and unburned carbon in the fly ash. Thermal NO_x formation in the burnout zone is small because of the lower temperature. Depending on the nature of the reburn fuel used, various boiler retrofits are required. The following equations represent the general chemistry of the process:

Primary Combustion Zone (Low to normal excess air; stoichiometric ratio of 1.1-1.2) –

Reburn Zone (Fuel-rich; stoichiometric ratio of 0.85-0.95) –

Burnout Zone (Normal excess air; stoichiometric ratio of 1.20-1.25) –

See also: Combustion.

Recoverable Reserves

Recoverable reserves (Table R-5) are that portion of resource reserves that are economically and technically feasible to extract at the existing price of the resource commodity.

Table R-5 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Non-recoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Recoverable reserves fluctuate with the price of the commodity. Resources are considered recoverable reserves if they can be developed with reasonable certainty from a given date under current economic conditions, operating methods, and government regulations.

Resource reserves have specific classifications related to the degree of certainty with which they can be recovered, based on seismic and engineering data. Degrees of uncertainty are expressed by dividing oil reserves into two primary classifications, proven and unproven.

See also: Reserves.

Recovery Boiler

A recovery boiler is a pulp mill boiler in which lignin and spent cooking liquor (black liquor) are burned to generate steam. A recovery boiler is the part of Kraft process of pulping where chemicals for white liquor are recovered and reformed from black liquor, which contains lignin from previously processed wood.

Concentrated black liquor contains organic dissolved wood residue in addition to sodium sulfate from the cooking chemicals added at the digester, and combustion of the organic portion of chemicals produces heat. In the recovery boiler, heat is used to produce high-pressure steam, which is used to generate electricity in a turbine. The turbine exhaust, low-pressure steam is used for process heating.

Combustion of black liquor in the recovery boiler furnace needs to be controlled carefully. The high concentration of sulfur requires optimum process conditions to avoid production of sulfur dioxide and reduced sulfur gas emissions. In addition to environmentally clean combustion, reduction of inorganic sulfur must be achieved in the char bed.

See also: Black Liquor, Combustion, Kraft Process.

Recovery Processes

An important aspect of energy generation (as waste product disposal) from any source is the application of the appropriate recovery process.

Recovery Processes Applicable to Gas Streams

The contaminants in waste gas streams can be gases, liquids, or solids and must be removed from the gas stream prior to discharge to the atmosphere if they provide a hazard to human health or the environment or if their loss represents major financial burden, as with some valuable materials. Typical examples of hazardous gases are toxic materials such as carbon monoxide, hydrogen sulfide, and hydrogen cyanide, as well as environmentally undesirable gases such as oxides of nitrogen and sulfur and vapors from hazardous liquids such as paint solvents, gasoline, and halogenated cleaning solvents. The liquids in gases are all in the form of mists or fogs either caused by entrainment from gas-liquid contacting or by condensation of vapors in the gas stream due to cooling. Finally, the solids are usually in the form of dusts entrained in the gas stream.

Recovery of Gases from Gas Streams

The separation of homogeneous gas mixtures requires either some way of generating a second equilibrium phase or a technique which takes advantage of differing rates of reaction or of mass transport of the components of the gas mixture. At the present time, the techniques most frequently used in waste minimization depend on generation of a second phase, although membrane processes that depend on relative mass transport rates may become of increasing importance in gas recycling operations in the future.

The common ways of generating the second phase are (i) the use of a solid sorbent such as activated carbon, or (ii) the use of a liquid solvent selective for the undesirable contaminant (Table R-6).

Table R-6 Processes for the recovery of gases from gas streams.

Process	Description
Absorption	Absorption, stripping, and scrubbing
Adsorption	Adsorption, ion exchange, reversible reaction with solids
Chemical reaction	Adsorption, ion exchange, reversible reaction with solids
Permeation	Membrane processes
Scrubbing	Absorption, stripping, and scrubbing

These materials can work either by physical or chemical interaction with the contaminants. For example, solid adsorbents can attract an adsorbed phase merely by the physical nature of its surface structure or by building into the adsorbent a chemical functionality which reacts with specific materials in the gas phase to sequester them. Similarly, the addition of a solvent can lead to a physical separation process or a chemical one. For example, in absorption and scrubbing with liquid solvents, the solvent can either provide a liquid phase to permit separation of the gas mixture by physical distillation, or can actually react chemically with one or more of the contaminants in the feed gas to bind them chemically into the solvent phase. Both types of adsorbents and solvents are in common use.

Recovery of Liquids from Gas Streams

As mentioned above, the liquids found in gases are usually in the form of mists or fogs and can be removed effectively by mechanical means. The basic problem with mists and fogs is to coalesce the tiny liquid droplets into larger drops that can be more readily removed from the gas phase by settling. This can be done by the addition of ultrasonic energy to the gas phase, by passing the gas phase through a cyclone to centrifuge out the liquid, by impacting the droplets on a solid surface such as metal mesh demisters and coalescers, or by contacting the droplets with a liquid surface such as exists in scrubbers and absorbers (Table R-7).

Table R-7 Processes for the recovery of liquids from gas streams.

Process	Description
Absorption	Absorption, stripping, and scrubbing
Coalescence	Settling and flotation
Condensation	Distillation
Cyclones	Centrifuging and cycloning
Electrostatics	Electrostatic preoccupation, electrochemical processes
Filtration	Filtration and drying
Scrubbing	Absorption, stripping, and scrubbing

Recovery of Solids from Gas Streams

The entrainment of solids in gases is in the form of fine particles classed as dusts. Since they form a second phase, as with liquids in gases, they are also separated by mechanical techniques. Large particles can be readily settled out of a gas phase, but dust-like particles generally require some form of mechanical help. This mechanical help can take the form of cyclones, filters, scrubbers, or electrostatic precipitators, and all are in common use (Table R-8).

Table R-8 Processes for the recovery of solids from gas streams.

Process	Description
Cyclones	Centrifuging and cycloning
Electrostatics	Electrostatic preoccupation, electrochemical processes
Filtration	Filtration and drying
Scrubbing	Absorption, stripping, and scrubbing

Recovery Processes Applicable to Liquid Streams

The contaminants in liquid streams may also be either gases, liquids, or solids. Furthermore, the liquid streams may be either homogeneous or heterogeneous, depending on whether the contaminants are in solution or form a second phase. The gases are easily settled out by gravity unless they are dissolved, of small bubble size, or the liquid is extremely viscous. Heterogeneous liquid phases often exist as clouds of very tiny droplets in a continuous phase of a second liquid. These systems can be difficult to separate by mechanical means, especially if the densities of the droplets and of the continuous phase are close to each other. Finally, solid contaminants can also be either dissolved in a liquid phase or exist as a slurry of solid particles in the liquid carrier. The optimum separation process for recovery of each of these contaminants depends on the exact nature of the contaminated liquid. Recovery of the three different phases of contaminant is discussed below.

Recovery of Gases from Liquid Streams

When gases exist as a separate phase in liquids, they can usually be recovered by coalescing the entrained gas bubbles into large bubbles and letting them settle out of the liquid phase. If necessary, the viscosity of the continuous liquid phase can be reduced by heating to improve both coalescing and settling. On the other hand, if the gases are dissolved in the liquid phase, some sort of carrier phase must be generated to strip the dissolved gases out of the liquid. This can be an inert gas, such as steam, air, carbon dioxide, or nitrogen, blown through the liquid phase as a stripping gas in a stripping column. Alternatively, vapors generated from the liquid by heating it to a boil as in flash distillation can be used to strip out gases. In this latter case, the stripping gases are the vapors generated by the boiling liquid.

Recovery of Liquids from Liquid Streams

As with gaseous contaminants, liquid contaminants can also exist in liquid systems as either a separate liquid phase or as a homogeneous solution. When a heterogeneous system is encountered, the recovery processes are mechanical in nature such as settling, flotation, coalescing, cycloning, and centrifuging. On the other hand, if the system is homogeneous, either equilibrium- or rate-controlled processes must be used. The equilibrium processes are distillation, stripping, adsorption, extraction and supercritical extraction, ion exchange, and solvent precipitation. Finally, the rate-controlled processes are membrane diffusion and electrolytic processes (Table R-9).

Table R-9 Processes for the recovery of liquids from liquid streams.

Process	Description
Adsorption	Adsorption, ion exchange, reversible reaction with solids
Centrifuging	Centrifuging and cycloning
Cyclones	Centrifuging and cycloning
Distillation	Thermal fractionation
Extraction	Solvent extraction, solvent precipitation, and leaching
Flotation	Flotation and settling
Ion exchange	Adsorption, ion exchange, reversible reaction with solids

(Continued)

Table R-9 Processes for the recovery of liquids from liquid streams. (*Continued*)

Process	Description
Permeation	Membrane processes
Settling	Flotation and settling
Solvent precipitation	Solvent extraction, solvent precipitation, and leaching
Stripping	Adsorption, stripping, and scrubbing
Reverse osmosis	Membrane processes
Ultrafiltration	Membrane processes

Recovery of Solids from Liquid Streams

Solid contaminants can also exist in liquids either as slurries or in the dissolved state. As with other heterogeneous systems, the slurries are separated by mechanical techniques such as settling, filtration, flocculation, flotation, centrifuging, and drying. With the homogeneous systems, evaporation and crystallization are frequently used to generate a heterogeneous system followed by one of the techniques for heterogeneous systems (Table R-10).

Table R-10 Processes for the recovery of solids from liquid streams.

Process	Description
Centrifuging	Centrifuging and cycloning
Chemical precipitation	Chemical precipitation and sedimentation
Crystallization	Evaporation and crystallization
Cyclones	Centrifuging and cycloning
Drying	Filtration and drying
Evaporation	Evaporation and crystallization
Filtration	Filtration and drying
Flocculation	Chemical precipitation and sedimentation
Flotation	Flotation and settling
Microfiltration	Membrane processes
Settling	Flotation and settling
Ultrafiltration	Membrane processes

Recovery Processes From Solid Streams

Solids can be contaminated with relatively small amounts of adsorbed gases liquids as with spent adsorbents, or with larger amounts of liquids as with cakes and sludges. Furthermore, solids can absorb either liquids or gases give swollen solids and gels. Solid polymers can show this latter behavior, and solids can exist as mixtures with other solids as in the case of many domestic and industrial solid wastes. All of these systems are discussed below.

Recovery of Gases from Solid Streams

Adsorbed gases can be recovered from solids by stripping the solids with a sensible gas such as steam. This permits the adsorbed gas to be recovered condensing the steam out of it. Alternatively, if the adsorbed gas is readily condensable, as with some vapors, fixed gases such as air, nitrogen, or carbon dioxide can be used for stripping. The desorbed vapors are recovered from the stripping gas by condensing them out of the stripping gas stream.

Dissolved gases require that the structure of the solid be changed to discharge the dissolved gases. This can frequently be done by raising the temperature of the solid during stripping to raise the partial pressure of the dissolved gases.

Recovery of Liquids from Solid Streams

Adsorbed liquids on solids can be recovered by stripping with immiscible condensable gases in much the same way as adsorbed gases (Table 3.6). However, they can also be washed off the solids with suitable solvents and then recovered from the resulting mixture with the solvent. Dissolved liquids may be recovered by heating the solids in a dryer under a stream of stripping gas.

Recovery of Solids from Solid Streams

Mixtures of solids use much different processes for separation from those used with liquids and gases. The usual separation processes are based on differences in density, particle size, surface properties, magnetic susceptibility, or electrostatic characteristics of the various solids (Table R-11).

Table R-11 Processes for the recovery of liquids from solid streams.

Process	Description
Centrifuging	Centrifuging and cycloning
Cyclones	Centrifuging and cycloning
Drying	Filtration and drying
Evaporation	Evaporation and crystallization
Extraction	Solvent extraction, solvent precipitation, and leaching
Filtration	Filtration and drying
Stripping	Absorption, stripping, and scrubbing

For example, with elutriation, in which a stream of gas is passed through a fluidized bed of solids of differing particle sizes and particle densities, the gas carries out with it the lightest and smallest particles first and can be used to make either a density separation or a particle size separation (Table R-12).

Table R-12 Processes for the recovery of solids from solid streams.

Process	Description
Electromagnetic	Separation of solids
Electrostatic	Separation of solids
Elutriation	Flotation and settling
Flotation	Flotation and settling
Screening	Separation of solids
Sorting	Separation of solids

Surface properties can be used to make a separation as with froth flotation in which dispersed air is bubbled through a slurry of a solid mixture in water and attaches bubbles of air to the solid particles selectively according to the surface properties of the individual solid particles. This makes the particles with the attached bubbles buoyant and carries them to the surface from which they can be recovered. The process is commonly used on a large scale in the mining industry to separate ores. Finally, electrostatic and magnetic separations of solids are frequently done on a moving belt which sorts materials according to their magnetic properties or their ability to accept an electrostatic charge (Table 3.7).

Process Selection

There are several general rules of thumb for decreasing energy consumption in separation processes. These rules of thumb were primarily aimed at process design, but they also give some insights into choosing processes and process equipment (Table R-13).

Table R-13 General rules for process selection.

1. Perform the mechanical separations first if more than one phase exists in the feed.
2. Avoid overdesign and use designs giving efficient turndown. Favor simple processes.
3. Favor processes transferring the minor rather than major component between phases,
3. Favor high separation factors.
4. Recognize value differences of energy in different forms and of heat and cold at different temperature levels,
6. Investigate use of heat pump, vapor compression, or multi-effects for separations with small temperature ranges.
7. Use staging or countercurrent flow where appropriate.
8. For similar separation factors, favor energy-driven processes over mass-separating agent processes.
9. For energy-driven processes, favor those with lower latent heat of phase change.

Mechanical separations such as settling, screening, filtration, centrifugation, flocculation, etc., are much less energy intensive than separation processes for homogeneous mixtures. Therefore, it is usually preferred to perform the separation of heterogeneous phases such as sludges and emulsions first before attacking the homogeneous mixtures. The removal of heterogeneous phases greatly simplifies the separation of homogeneous mixtures.

Most of the separation processes encountered in hazardous waste minimization are fairly simple, such as batch distillation, adsorption, settling, filtration, and the like. These have good turndown ratios, i.e., they can operate efficiently over a wide range of operating rates. It is important to have this capability, particularly for continuous processes such as wastewater treating and stack gas scrubbing where flow rates change in response to manufacturing operations.

Processes with high separation factors are important in making separation processes economical. It applies to many of the separations involved in waste minimization. For very dilute systems, there is a great advantage to using processes like ion exchange and adsorption for the impurity rather than evaporation of the water. Furthermore, for extraction type processes, it is better to extract the minor component rather than the major component to minimize solvent circulation and regeneration.

High separation factors greatly reduce the number of stages and thus the capital costs required for a separation (Rule 4). They can frequently be increased to essentially infinity by adding a specific reagent that only reacts with one component of the feed mixture. Examples of processes having high separation factors are ion exchange for demineralizing water, chemical complexing for mixtures of olefins and paraffins, adsorption of aromatics from mixtures with saturated hydrocarbons, and to a lesser extent adding a selective solvent to a distillation to convert it to an extractive distillation. Many waste streams, such as solvents in motor oils, have a naturally high separation factor for distillation due to the large difference in boiling point between the homogeneous feed components. These solvents can be recovered in satisfactory purity for recycling in single-stage batch stills, and many such operations are already in place.

Heat and refrigeration energy are inherently less expensive than electrical energy or mechanical work. However, as the temperature at which the heat or refrigeration is used departs from ambient temperature, the cost of heat and refrigeration increases and these effects should be considered in choosing a separation process for a given feed mixture.

While mechanical work is more expensive than heat or refrigeration, it can sometimes permit latent heat of condensation to be exchanged for latent heat of vaporization. In such a case, which usually requires a small temperature

difference between the heat source and heat sink, vapor compression by mechanical work on the distillate can give it an increased pressure and condensing temperature, actually higher than the temperature in the boiler. This pumping of heat from a lower to a higher temperature permits the vapor to be condensed in the boiler generating the vapor in the first place. A balance between compressor cost and heat cost can determine the desirability of such operation. Staging and countercurrent flow can decrease the amount of separating agent needed and increase the purity of the products.

Energy-driven processes are inherently more efficient because they are more nearly reversible. They have the additional advantage that the energy can be readily removed by exchange with another stream and recycled to the process. This can be used to cascade the energy through a series of separations at gradually reducing temperature from initial source to final sink, using it over and over, thus minimizing the required supply of energy. To do the same type of thing with a mass separating agent requires an additional separation process for each exchange or recovery of the mass separating agent, thereby requiring much more energy.
